Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To our spouses:
Patricia, Roslyn, and Larry

the Martin children and grandchild
Scott & Molly; Sonya, Peter, & Mateo,

the Fanaroff children and grandchildren
Jonathan & Kristy; Jodi, Peter, Austin, & Morgan;
and Amanda, Jason, & Jackson,

and the Walsh children
Sean and Ryan

with love, admiration, and deep appreciation
for their continued support and inspiration

Contributors

Jalal M. Abu-Shaweesh, MBBS

Associate Professor of Pediatrics, Case Western Reserve University; Attending Neonatologist, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Respiratory Disorders in Preterm and Term Infants

Veronica H. Accornero, PhD

Assistant Professor of Clinical Pediatrics, University of Miami Miller School of Medicine, Miami, Florida

Infants of Substance-Abusing Mothers

Heidelise Als, PhD

Associate Professor of Psychiatry (Psychology), Harvard Medical School; Director of Neurobehavioral Infant and Child Studies, and Senior Associate in Psychiatry, Children's Hospital; Research Associate in Newborn Medicine, Brigham & Women's Hospital; Consulting Staff in Pediatric Psychology, Spaulding Rehabilitation Hospital, Boston, Massachusetts

Neurobehavioral Development of the Preterm Infant

Brenna L. Anderson, MD, MSCR

Assistant Professor of Obstetrics and Gynecology, Division of Maternal Fetal Medicine, Warren Alpert Medical School of Brown University, Providence, Rhode Island; Medical Staff, Women & Infant's Hospital, Pittsburgh, Pennsylvania; Consulting Physician, South County Hospital, South Kingstown, Rhode Island; Consulting Physician, Charlton Hospital, Fall River, Massachusetts

Perinatal Infections

Jacob V. Aranda, MD, PhD, FRCP(C)

Professor and Director, Neonatology, State University of New York Downstate Medical Center, Brooklyn, New York

Developmental Pharmacology

James E. Arnold, MS, FAAP

The Julius W. McCall Professor and Chair, Department of Otolaryngology, Head and Neck Surgery, Case Western Reserve University; Chairman, Department of Otolaryngology, University Hospitals Case Medical Center, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Upper Airway Lesions

Sundeep Arora, MD

Attending Pediatric Gastroenterologist, Children's Hospitals and Clinics of Minnesota; Minnesota Gastroenterology, St. Paul, Minnesota

Disorders of Digestion

Komal Bajaj, MD

Reproductive Genetics Fellow, MonteFiore Medical Center, Albert Einstein College of Medicine, Bronx, New York; Research Associate, Human Genetics Laboratory at Jacobi Medical Center, Bronx, New York

Genetic Aspects of Perinatal Disease and Prenatal Diagnosis

Jill E. Baley, MD

Professor of Pediatrics, Case Western Reserve University School of Medicine; Medical Director, Neonatal Transitional Unit, Division of Neonatology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Perinatal Viral Infections; Schedule for Immunization of Preterm Infants

Eduardo H. Bancalari, MD

Professor of Pediatrics, University of Miami, Miller School of Medicine; Director, Division of Neonatology, University of Miami/Jackson Memorial Hospital, Miami, Florida

Bronchopulmonary Dysplasia

Emmalee S. Bandstra, MD

Professor of Pediatrics and Obstetrics and Gynecology, University of Miami Miller School of Medicine; Attending Neonatologist, Jackson Memorial Medical Center, Holtz Children's Hospital, Miami, Florida

Infants of Substance-Abusing Mothers

Edward M. Barksdale, Jr., MD

Professor of Surgery, Case Western Reserve University; Chief, Division of Pediatric Surgery, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Selected Gastrointestinal Anomalies

Cynthia F. Bearer, MD, PhD

Mary Gray Cobey Professor of Neonatology, University of Maryland School of Medicine; Chief, Division of Neonatology, University of Maryland Medical System, Baltimore, Maryland

Occupational and Environmental Risks to the Fetus

Isaac Blickstein, MD

Professor, Hadassah-Hebrew University School of Medicine, Jerusalem, Israel; Senior Physician, Department of Obstetrics and Gynecology, Kaplan Medical Center, Rehovot, Israel

Fetal Effects of Autoimmune Disease; Obstetric Management of Multiple Gestation and Birth; Post-term Pregnancy

Jeffrey L. Blumer, MD, PhD

Professor of Pediatrics and Pharmacology,
Case School of Medicine;
Department of Pediatrics, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Developmental Pharmacology

Samantha Butler, PhD

Instructor, Harvard Medical School; Staff Psychologist, Children's Hospital Boston, Boston, Massachusetts

Neurobehavioral Development of the Preterm Infant

Kara Calkins, MD

Clinical Instructor, David Geffen School of Medicine at UCLA, University of California; Attending Physician, Mattel Children's Hospital at UCLA, Department of Pediatrics, Division of Neonatology and Developmental Biology, Los Angeles, California

Developmental Origins of Adult Health and Disease

Michael S. Caplan, MD

Clinical Professor of Pediatrics, University of Chicago,
Pritzker School of Medicine, Chicago, Illinois;
Chairman, Department of Pediatrics, North Shore
University Health System, Evanston, Illinois

Neonatal Necrotizing Enterocolitis: Clinical Observations, Pathophysiology, and Prevention

Waldemar A. Carlo, MD

Edwin M. Dixon Professor of Pediatrics; Director, Division of Neonatology, University of Alabama at Birmingham School of Medicine; Director, Newborn Nurseries, University of Alabama at Birmingham Medical Center, The Children's Hospital of Alabama, Birmingham, Alabama

Assessment of Pulmonary Function

Gisela Chelimsky, MD

Assistant Professor of Pediatrics, Case School of Medicine; Attending Physician, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Disorders of Digestion

Valerie Y. Chock, MD

Instructor of Neonatology, Stanford University School of Medicine, Stanford, California

Biomedical Engineering Aspects of Neonatal Monitoring

Walter J. Chwals, MD

Professor of Surgery and Pediatrics, Tufts University School of Medicine, Boston, Massachusetts

Development and Basic Physiology of the Neonatal Gastrointestinal Tract; Selected Gastrointestinal Anomalies

Alan R. Cohen, MD, FACS, FAAP

Reinberger Chair in Pediatric Neurological Surgery; Professor of Neurological Surgery and Pediatrics, Case Western Reserve University School of Medicine; Surgeon-in-Chief and Chief of Pediatric Neurological Surgery, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Disorders in Head Shape and Size; Myelomeningocele

Daniel R. Cooperman, MD

Professor of Orthopedic Surgery, Case Western Reserve University; Professor of Orthopedic Surgery, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Musculoskeletal Disorders; Bone and Joint Infections; Congenital Abnormalities of the Upper and Lower Extremities and Spine

Timothy M. Crombleholme, MD

Richard G. and Geralyn Azizkhan Chair in Pediatric Surgery; Professor of Surgery, Pediatrics (Molecular and Developmental Biology), and Obstetrics and Gynecology, University of Cincinnati College of Medicine; Director, Fetal Care Center of Cincinnati, Division of Pediatric General, Thoracic, and Fetal Surgery, Cincinnati Children's Hospital, Cincinnati, Ohio

Surgical Treatment of the Fetus

Mario De Curtis, MD

Professor of Neonatology, Dipartimento di Scienze Ginecologiche, Perinatologia e Puericultura, University of Rome Faculty of Medicine; Director, Neonatology Unit, Patologia Neonatale e Terapia Intensiva Dipartimento di Scienze Ginecologiche, Perinatologia e Puericultura, Azienda Policlinico Umberto I, Rome, Italy

Disorders of Calcium, Phosphorus, and Magnesium Metabolism

Linda S. de Vries, MD, PhD

Professor in Neonatal Neurology, Department of Neonatology, Wilhelmina Children's Hospital, Utrecht, The Netherlands

Intracranial Hemorrhage and Vascular Lesions; Hypoxic-Ischemic Encephalopathy, Assessment Tools

Katherine MacRae Dell, MD

Associate Professor of Pediatrics, Case Western Reserve University; Chief, Division of Pediatric Nephrology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Fluid and Electrolyte Management; Acid-Base Management; The Kidney and Urinary Tract

Scott Denne, MD

Professor of Pediatrics, Indiana University School of Medicine, Riley Hospital for Children, Indianapolis, Indiana

Parenteral Nutrition; Enteral Nutrition

Sherin U. Devaskar, MD

Professor of Pediatrics, David Geffen School of Medicine at UCLA; Director, Neonatal Research Center, Division of Neonatology and Developmental Biology, Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, California

Developmental Origins of Adult Health and Disease; Disorders of Carbohydrate Metabolism

Juliann Di Fiore, BSEE

Research Engineer, Department of Medicine, Case Western Reserve University, Division of Neonatology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Assessment of Pulmonary Function

Steven M. Donn, MD

Professor of Pediatrics, Division of Neonatal-Perinatal Medicine; Faculty Associate, Center for Global Health, School of Public Health, University of Michigan Health System; Staff Neonatologist, C.S. Mott Children's Hospital, Ann Arbor, Michigan

Assisted Ventilation and Its Complications

Morven S. Edwards, MD

Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas

Postnatal Bacterial Infections; Fungal and Protozoal Infections

William H. Edwards, MD

Professor of Pediatrics, Dartmouth Medical School, Hanover, New Hampshire; Vice Chairman, Department of Pediatrics, Neonatology Section Chief; Medical Director, Citad Nurseries, Dartmouth Hitchcock Medical Center, Lebanon, New Hampshire

Care of the Mother, Father, and Infant,

Francine Erenberg, MD

Assistant Professor, Cleveland Clinic Lerner College of Medicine of Case Western Reserve University; Staff, Pediatric Cardiologist, Cleveland Clinic Children's Hospital, Department of Pediatric Cardiology, Cleveland, Ohio

Fetal Cardiac Physiology and Fetal Cardiovascular Assessment; Congenital Defects

Avroy A. Fanaroff, MB, BCh, FRCP[E], FRCPCN

Professor, Pediatrics and Reproductive Biology, Case Western Reserve University School of Medicine; Eliza Henry Barnes Chair in Neonatology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Epidemiology; Perinatal Services; Obstetric Management of Prematurity

Jonathan M. Fanaroff, MD, JD

Assistant Professor of Pediatrics, Case Western Reserve University School of Medicine; Associate Medical Director, NICU; Director, Rainbow Center for Pediatric Ethics, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Legal Issues in Neonatal-Perinatal Medicine

Ross Fasano, MD

Pediatric Hematology/Oncology Fellow, Children's National Medical Center, Washington, DC

Blood Component Therapy for the Neonate

Orna Flidel-Rimon, MD

Lecturer in Pediatrics, Hebrew University, Jerusalem; Attending Physician, Kaplan Medical Center, Rehovot, Israel

Post-term Pregnancy

Smadar Friedman, MD

Senior Lecturer, Hadassah University Hospital, Hadassah School of Medicine; Director, Neonatology Unit, Department of Neonatology, Hadassah Ein Kerem Hospital, University Hospital, Jerusalem, Israel

Fetal Effects of Autoimmune Disease

Susan E. Gerber, MD, MPH

Assistant Professor, Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine, Northwestern University, Feinberg School of Medicine; Attending Physician, Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine, Northwestern Memorial Hospital, Chicago, Illinois

Antepartum Fetal Surveillance; Evaluation of the Intrapartum Fetus

Jay P. Goldsmith, MD

Clinical Professor of Pediatrics, Tulane University School of Medicine, New Orleans, Lousiana; Neonatologist, Women's and Children's Hospital, Lafayette, Louisiana

Delivery Room Resuscitation of the Newborn, Overview and Initial Management; Chest Compression, Medications, and Special Problems

Bernard Gonik, MD

Professor and Fann Srere Chair of Perinatal Medicine, Department of Obstetrics and Gynecology, Wayne State University School of Medicine, Detroit, Michigan

Perinatal Infections

Jeffrey B. Gould, MD

Robert L. Hess Professor in Pediatrics and Director, Perinatal Epidemiology and Health Outcomes Research Unit, Department of Pediatrics, Division of Neonatal and Developmental Medicine, Stanford University School of Medicine, Stanford; Attending Neonatologist, Lucile Packard Children's Hospital at Stanford, Palo Alto, California

Evaluating and Improving the Quality and Safety of Neonatal Intensive Care

Pierre Gressens, MD, PhD

Chief, Inserm-Paris 7 University, Hopital Robert Debré, Paris, France; Professor of Perinatal Neurology, Imperial College London, Hammersmith Hospital, London, United Kingdom

Normal and Abnormal Brain Development; White Matter Damage and Encephalopathy of Prematurity

Susan J. Gross, MD

Professor, Department of Obstetrics and Gynecology, Women's Health and Department of Pediatrics, Albert Einstein College of Medicine; Chairperson, Department of Obstetrics and Gynecology, North Bronx Healthcare Network, Bronx, New York

Genetic Aspects of Perinatal Disease and Prenatal Diagnosis

Andrée M. Gruslin, MD, FRCS

Associate Professor, Division of Maternal Fetal Medicine, Department of Obstetrics & Gynecology and Newborn Care, Cellular and Molecular Medicine, University of Ottawa, Ottawa, Ontario, Canada

Erythroblastosis Fetalis

Balaji K. Gupta, MD

Clinical Assistant Professor, Department of Ophthalmology and Visual Sciences, University of Chicago Pritzker School of Medicine, Chicago, Illinois

The Eye, Examination and Common Problems

Maureen Hack, MB, ChB

Professor of Pediatrics, Case School of Medicine; Director, High Risk Follow-Up Program, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Follow-up for High-Risk Neonates

Louis P. Halamek, MD

Associate Professor, Division of Neonatal and Developmental Medicine, Department of Pediatrics, Stanford University; Director, Center for Advanced Pediatric and Perinatal Education, Packard Children's Hospital, Palo Alto, California; Attending Neonatologist, Packard Children's Hospital, Palo Alto, California

Simulation in Neonatal-Perinatal Medicine

Aaron Hamvas, MD

The James P. Keating, MD, Professor of Pediatrics, Washington University School of Medicine, St. Louis Children's Hospital, St. Louis, Missouri

Pathophysiology and Management of Respiratory Distress Syndrome

Jonathan Hellmann, MBBCh, FCP(SA), FRCPC, MHSc

Professor of Pediatrics, University of Toronto; Clinical Director, Neonatal Intensive Care Unit, Hospital for Sick Children, Toronto, Ontario, Canada

Medical Ethics in Neonatal Care

Susan R. Hintz, MD

Associate Professor, Department of Pediatrics, Division of Neonatal and Perinatal Medicine, Stanford University School of Medicine; Attending Neonatologist, Lucile Packard Children's Hospital, Stanford, California

Biomedical Engineering Aspects of Neonatal Monitoring

Steven B. Hoath, MD

Professor of Pediatrics, University of Cincinnati College of Medicine, Division of Neonatology; Medical Director, Skin Sciences Program, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

The Skin

Jeffrey D. Horbar, MD

Jerold F. Lucey Professor of Neonatal Medicine, University of Vermont College of Medicine; Chief Executive and Scientific Officer, Vermont Oxford Network, Burlington, Vermont

Evaluating and Improving the Quality and Safety of Neonatal Intensive Care

McCallum R. Hoyt, MD, MBA

Assistant Professor of Anesthesiology, Harvard Medical School, Boston, Massachusetts; Director of Gynecologic and Ambulatory Anesthesia; Staff, Obstetric Anesthesia, Brigham and Women's Hospital, Boston, Massachusetts

Anesthetic Options for Labor and Delivery

Petra S. Hüppi, MD

Professor of Pediatrics, University of Geneva Faculty of Medicine; Director, Child Development Unit, Department of Pediatrics, Children's Hospital, Geneva, Switzerland

White Matter Damage and Encephalopathy of Prematurity; Normal and Abnormal Brain Development

Lucky Jain, MD, MBA

Richard W. Blumberg Professor and Executive Vice Chairman, Department of Pediatrics, Emory University School of Medicine; Medical Director, Emory Children's Center, Children's Healthcare of Atlanta at Eggleston in Atlanta, Georgia, Emory University Hospital Midtown, Atlanta, Georgia

The Late Preterm Infant

Alan H. Jobe, MD, PhD

Professor of Pediatrics, University of Cincinnati School of Medicine; Director of Perinatology Research, Cincinnati Children's Hospital, Cincinnati, Ohio

Lung Development and Maturation

Nancy E. Judge, MD, FACOG

Associate Professor of Reproductive Biology, Albert Einstein Medical School of Yeshiva University; Director of Obstetrics, Montefiore North Division, Montefiore Hospitals, Bronx, New York

Perinatal Imaging

Michael Kaplan, MD

Professor of Pediatrics, Faculty of Medicine of the Hebrew University; Director, Department of Neonatology, Shaare Zedek Medical Center, Jerusalem, Israel

Neonatal Jaundice and Liver Disease

Satish C. Kalhan, MBBS, FRCP, DCH

Professor, Department of Molecular Medicine; Staff, Department of Pathobiology, Gastroenterology and Hepatology, Cleveland Clinic Lerner College of Medicine of Case Western Reserve University Cleveland, Ohio

Disorders of Carbohydrate Metabolism

Reuben Kapur, PhD

Professor of Pediatrics, Molecular Biology and Biochemistry, Medical and Molecular Genetics, Microbiology and Immunology, Indiana University School of Medicine, Department of Pediatrics; Director, Program in Hematologic Malignancies and Stem Cell Biology, Herman B. Wells Center for Pediatric Research, Cancer Research Institute, Indiana University School of Medicine, Indianapolis, Indiana

Developmental Immunology

Ganga Karunamuni, MD

Graduate Research Assistant, Case Western Reserve University,Cleveland, Ohio

Cardiac Embryology

Lawrence M. Kaufman, MD

Clinical Associate Professor of Ophthalmology, University of Illinois at Chicago; Director of Pediatric Ophthalmology, Advocate Illinois Masonic Medical Center, Chicago, Illinois

Examination and Common Problems

Kathleen A. Kennedy, MD, MPH

Professor of Pediatrics, Department of Pediatrics, University of Texas Health Science Center at Houston; Director, Division of Neonatal-Perinatal Medicine; Director, M.S. in Clinical Research Degree Program, University of Texas Health Science Center at Houston, Texas

Practicing Evidence-Based Neonatal-Perinatal Medicine

John H. Kennell, MD

Professor of Pediatrics Emeritus, Department of Pediatrics, Case School of Medicine; Attending Physician, Division of Behavioral Pediatrics, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Care of the Mother, Father, and Infant

Joseph A. Kitterman, MD

Professor of Pediatrics, University of California, San Francisco, School of Medicine, San Francisco, California

Fibrodysplasia Ossificans Progressiva

Marshall H. Klaus, MD

Professor of Pediatrics, Emeritus, University of California, San Francisco, School of Medicine, San Francisco, California

Care of the Mother, Father, and Infant,

Robert M. Kliegman, MD

Professor and Chair of Pediatrics, Medical College of Wisconsin; Pediatrician-in-Chief/Pamela and Leslie Muma Chair in Pediatrics, Children's Hospital of Wisconsin, Children's Corporate Center, Milwaukee, Wisconsin

Intrauterine Growth Restriction

Oded Langer, MD, PhD

Professor, Department of Obstetrics and Gynecology, Columbia University; Chairman, Department of Obstetrics and Gynecology, St. Luke's-Roosevelt Hospital Center, New York, New York

Pregnancy Complicated by Diabetes Mellitus

Noam Lazebnik, MD

Associate Professor of Reproductive Biology, Case Western University School of Medicine; Division of Maternal and Fetal Medicine, University MacDonald Women's Hospital, Cleveland, Ohio

Perinatal Imaging

Malcolm I. Levene, MD, FMedSe

Professor of Paediatrics and Child Health, University of Leeds School of Medicine Department of Pediatrics; Consultant Neonatologist, Leeds Teaching Hospitals NHS Trust, Leeds, West York, United Kingdom

Hypoxic-Ischemic Encephalopathy; Pathophysiology; Management

Foong-Yen Lim, MD

Assistant Professor of Surgery, Pediatrics and Obstetrics and Gynecology, University of Cincinnati College of Medicine; Pediatrics and Fetal Surgeon, Division of Pediatric General, Thoracic and Fetal Surgery, Cincinnati Children's Hospital, Cincinnati, Ohio

Surgical Treatment of the Fetus

Tom Lissauer, MB, Bchir, FRCPCH

Hon Consultant Neonatologist, Imperial College Healthcare Trust; Pediatric Program Director, Institute of Global Health, Imperial College, London, United Kingdom

Physical Examination of the Newborn

Suzanne M. Lopez, MD

Associate Professor of Pediatrics, Department of Pediatrics, University of Texas Health Science Center at Houston; Associate Professor of Pediatrics; Director, Neonatal Perinatal Medicine Fellowship, University of Texas Health Science Center at Houston, Houston, Texas

Practicing Evidence-Based Neonatal-Perinatal Medicine

Timothy E. Lotze, MD

Assistant Professor, Department of Pediatrics, Baylor College of Medicine; Section of Child Neurology, Texas Children's Hospital, Houston, Texas

Hypotonia and Neuromuscular Disease

Naomi L. C. Luban, MD

Division Chief, Children's National Medical Center, Department of Laboratory Medicine, Children's National Medical Center, Washington, DC

Blood Component Therapy for the Neonate

Lori Luchtman-Jones, MD

Associate Professor, George Washington University Medical School; Division Chief, Hematology, Children's National Medical Center, Washington, DC

Hematologic Problems in the Fetus and Neonate

David K. Magnuson, MD, FACS, FAAP

Department Chair, Pediatric Surgery, Cleveland Clinic Children's Hospital, Cleveland, Ohio

Development and Basic Physiology of the Neonatal Gastrointestinal Tract; Selected Gastrointestinal Anomalies

Henry H. Mangurten, MD

Professor of Pediatrics, Rosalind Franklin University of Medicine and Science/The Chicago Medical School, North Chicago, IL; Chairman Emeritus, Department of Pediatrics, Advocate Lutheran General Children's Hospital, Park Ridge, Illinois

Birth Injuries

Jacquelyn McClary, Pharm D

Clinical Pharmacist Specialist, Neonatal Intensive Care Unit, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Developmental Pharmacology

Geoffrey Miller, MA, MB, BCh, MPhil, MD, FRCP, FRACP

Professor of Pediatrics and Neurology, Yale University School of Medicine; Clinical Director, Pediatric Neurology, Yale New Haven Hospital, New Haven, Connecticut

Hypotonia and Neuromuscular Disease

Marilyn T. Miller, MD

Professor of Ophthalmology, Department of Ophthalmology and Visual Sciences, University of Illinois at Chicago College of Medicine; University of Illinois Hospital, Chicago, Illinois

The Eye, Examination and Common Problems

Mohamed W. Mohamed, MD

Neonatology Fellow, The Hospital for Sick Children, Toronto, Ontario

Disorders of Calcium, Phosphorus, and Magnesium Metabolism

Thomas R. Moore, MD

Professor and Chairman, Department of Reproductive Medicine, University of California School of Medicine, San Diego, California

Erythroblastosis Fetalis; Amniotic Fluid and Nonimmune Hydrops Fetalis

Colin J. Morley MA, DCH, MD, FRCP, FRCPCH, FRACP

Professor of Neonatal Medicine, The Royal Women's Hospital, Melbourne, Australia, United Kingdom

Role of Positive Pressure Ventilation in Neonatal Resuscitation

Stuart C. Morrison, MD, ChB, FRCP

Clinical Faculty, Cleveland Clinic Medical School; Staff Radiologist, Cleveland Clinic Foundation, Cleveland, Ohio

Perinatal Imaging

Anil Narang, MD

Professor, Pediatrics (Neonatology), Department of Pediatrics, Postgraduate Institute of Medical Education and Research; Head, Department of Pediatrics, Advanced Pediatric Centre, Chandigarh, India

Perinatal and Neonatal Care in Developing Countries

Vivek Narendran, MD, MRCP, MBA

Associate Professor of Pediatrics, University of Cincinnati College of Medicine; Medical Director, University Hospital NICU, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

The Skin

Mary L. Nock, MD

Assistant Professor, Department of Pediatrics, Case Western Reserve University School of Medicine; Attending Neonatologist, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Tables of Normal Values

Mark R. Palmert, MD, PhD

Associate Professor of Paediatrics, University of Toronto Faculty of Medicine; Head, Division of Endocrinology, The Hospital for Sick Children, Toronto, Ontario, Canada

Disorders of Sex Development

Aditi S. Parikh, BA, MD

Clinical Instructor, Case Western Reserve University School of Medicine; Clinical Geneticist, University Hospital's Case Medical Center, Cleveland, Ohio

Congenital Anomalies

Robert L. Parry, MD

Associate Professor of Surgery and Pediatrics, Case Western Reserve School of Medicine; Pediatric Surgeon, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Development and Basic Physiology of the Neonatal Gastrointestinal Tract; Selected Gastrointestinal Anomalies

Dale L. Phelps, MD

Professor of Pediatrics, University of Rochester School of Medicine, Rochester, New York

Retinopathy of Prematurity

Brenda Poindexter, MD, MS

Associate Professor of Pediatrics, Indiana University School of Medicine, Riley Hospital for Children, Indianapolis, Indiana

Parenteral Nutrition; Enteral Nutrition

Richard A. Polin, MD

Professor of Pediatrics, Department of Neonatology, Columbia University Medical Center; Director, Division of Neonatology, Morgan Stanley Children's Hospital of New York, Columbia University Medical Center, New York, New York

Developmental Immunology

Bhagya L. Puppala, MD

Assistant Professor of Pediatrics, Rosalind Franklin University of Medicine and Science, The Chicago Medical School, North Chicago, Illinois; Adjunct Professor of Pediatrics, Midwestern University, Downer's Grove, Illinois; Director, Neonatal Perinatal Medicine-Fellowship, Director, Neonatal Perinatal Medicine Research, Advocate Lutheran General Children's Hospital, Park Ridge, Illinois

Birth Injuries

Tonse N.K. Raju, MD, DCH

Adjunct Professor of Pediatrics, Georgetown University, Washington, DC; Program Scientist/Medical Officer, Pregnancy and Perinatalogy Branch, Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, Maryland

From Infant Hatcheries to Intensive Care: Highlights of the Century of Neonatal Medicine

Ashwin Ramachandrappa, MD

Attending Neonatologist, Neonatology Associates, Ltd, Phoenix, Arizona

The Late Preterm Infant

Raymond W. Redline, MD

Professor of Pathology and Reproductive Biology, Case Western Reserve University School of Medicine; Pediatric Pathologist, University Hospital Case Medical Center, Cleveland, Ohio

Placental Pathology

Jacques Rigo, MD, PhD

Professor of Neonatology and Pediatrics Nutrition, University of Liège; Head, Department of Neonatology, CHR Citadelle, Liège, Belgium

Disorders of Calcium, Phosphorus, and Magnesium Metabolism

Barrett K. Robinson, MD, MPH

Clinical Fellow, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Northwestern University Feinberg School of Medicine, Chicago, Illinois

Evaluation of the Intrapartum Fetus

Susan R. Rose, MD

Professor of Pediatrics and Endocrinology, University of Cincinnati; Professor of Pediatric Endocrinology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Thyroid Disorders

Florence Rothenberg, MS, MD, FACC

Assistance Professor, Department of Internal Medicine Staff; Cardiologist, VAMC Division of Cardiovascular Diseases, University of Cincinnati, Cincinnati, Ohio

Cardiac Embryology

Shaista Safder, MD

Assistant Professor, University of Central Florida and Florida State University, Arnold Palmer Hospital for Children, Orlando, Florida

Disorders of Digestion

Ola Didrik Saugstad, MD, PhD, FRCPE

Professor of Pediatrics, Department of Pediatric Research, Oslo University, Oslo, Norway

Oxygen Therapy

Katherine S. Schaefer, PhD

Associate Professor of Biology, Randolph College, Lynchburg, Virginia

Cardiac Embryology

Mark S. Scher, MD

Professor of Pediatrics and Neurology, Case Western University School of Medicine; Division Chief, Pediatric Neurology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Seizures in Neonates

Gunnar Sedin, MD, PhD

Professor, Perinatal-Neonatal Medicine, Uppsala University School of Medicine, Uppsala, Sweden

The Thermal Environment

Dinesh M. Shah, MD

Professor, Department of Obstetrics/Gynecology; Director of Maternal-Fetal Medicine and Maternal-Fetal Medicine Fellowship, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Hypertensive Disorders of Pregnancy

Eric S. Shinwell, MD

Clinical Associate Professor of Pediatrics, Hebrew University, Jerusalem, Israel; Director of Neonatology, Kaplan Medical Center, Rehovot, Israel

Obstetric Management of Multiple Gestation and Birth

Rayzel M. Shulman, MD, FRCPC

Research Fellow, University of Toronto, The Hospital for Sick Children, Toronto, Ontario, Canada

Disorders of Sex Development

Eric Sibley, MD, PhD

Associate Professor of Pediatrics, Division of Pediatric Gastroenterology, Stanford University School of Medicine, Stanford, California

Neonatal Jaundice and Liver Disease

Sunil K. Sinha, MD, PhD

Professor of Pediatrics, University of Durham, Durham, United Kingdom; Consultant Neonatologist, The James Cook University Hospital, Middlesbroug, United Kingdom

Assisted Ventilation and Its Complications

Carlos J. Sivit, MD

Professor of Radiology and Pediatrics, Case Western Reserve School of Medicine; Vice Chair, Clinical Operations, University Hospitals Case Medical Center, Cleveland, Ohio

Diagnostic Imaging

Ernest S. Siwik, MD

Associate Professor of Clinical Pediatrics, Louisiana State University Health Sciences Center; Director, Cardiac Catheterization Program, Children's Hospital of New Orleans, New Orleans, Louisiana

Principles of Medical and Surgical Management

Robert C. Sprecher, MD, FACS, FAAP

Chief, Pediatric Otolaryngology, Rainbow Babies and Children's Hospital, Case Western Reserve University, Cleveland, Ohio

Upper Airway Lesions

Robin H. Steinhorn, MD

Raymond and Hazel Speck Berry Professor of Pediatrics, Northwestern University Steinberg School of Medicine; Vice Chair of Pediatrics, Division Head of Neonatology, Children's Memorial Hospital, Chicago, Illinois

Pulmonary Vascular Development

David K. Stevenson, MD

Harold K. Faber Professor of Pediatrics; Vice Dean, Stanford University School of Medicine; Senior Associate Dean for Academic Affairs, Department of Pediatrics, Division of Neonatal and Developmental Medicine, Stanford University School of Medicine; Director, Charles B. and Ann L. Johnson Center for Pregnancy and Newborn Services, Lucile Packard Children's Hospital, Stanford, California

Biomedical Engineering Aspects of Neonatal Monitoring; Neonatal Jaundice and Liver Disease

Eileen K. Stork, MD

Professor of Pediatrics, Case Western Reserve University School of Medicine; Director, Neonatal ECMO Program, Rainbow Babies and Children's Hospital, Division of Neonatology, Cleveland, Ohio

Therapy for Cardiorespiratory Failure

John E. Stork, MD

Assistant Professor, Case Western Reserve University; Chief, Pediatric Cardiac Anesthesia, Rainbow Babies and Children's Hospital, University Hospitals Case Medical Center, Cleveland, Ohio

Anesthesia in the Neonate

Arjan B. te Pas, MD, PhD

Assistant Professor, Leiden University Medical Center; Paediatrician-Neonatologist, Department of Pediatrics, Division of Neonatology, Leiden University Medical Center, Leiden, The Netherlands

Role of Positive Pressure Ventilation in Neonatal Resuscitation

George H. Thompson, MD

Professor, Orthopedic Surgery and Pediatrics, Case Western Reserve University; Director, Pediatric Orthopedics, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Musculoskeletal Disorders; Bone and Joint Infections; Congenital Abnormalities of the Upper and Lower Extremities and Spine

Philip Toltzis, MD

Professor of Pediatrics, Case Western Reserve University School of Medicine; Attending Pediatrician, Division of Pharmacology and Critical Care, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Perinatal Viral Infections

Robert Turbow, MD, JD

Adjunct Professor, Department of Biology, California Polytechnic State University, San Luis Obispo, California; Attending Neonatologist, Phoenix Children's Hospital, Phoenix, Arizona

Legal Issues in Neonatal-Perinatal Medicine

Jon E. Tyson, MD, MPH

UT Medical School Master's Program—Co Director; Director, Center for Clinical Research and Evidence-Based Medicine; UT Medical School; Michelle Bain Distinguished Professor, Memorial Hermann Hospital, Lyndon Baines Johnson Hospital, Houston, Texas

Practicing Evidence-Based Neonatal-Perinatal Medicine

George F. Van Hare, MD

Louis Larnck Ward Chair in Cardiology; Professor of Pediatrics; Director, Division of Pediatric Cardiology, Washington University School of Medicine, St. Louis Children's Hospital, St. Louis, Missouri

Neonatal Arrhythmias

Maximo Vento, MD, PhD

Professor of Pediatrics; Director, Neonatal Research Unit, University Hospital La Fe, Valencia, Spain

Oxygen Therapy

Dharmapuri Vidyasagar, MD, MSs, FAAP, FCCM, DHC

Professor Emeritus, University of Illinois at Chicago, Department of Pediatrics, Chicago, Illinois

Perinatal and Neonatal Care in Developing Countries

Beth A. Vogt, MD

Inborn Errors of Metabolism

Preface

The foundation for successful outcomes in neonatal-perinatal medicine has been the ability to apply knowledge of the fundamental pathophysiology of the various neonatal disorders to safe interventions. Molecular, biologic, and technologic advances have facilitated the diagnosis, monitoring, and therapy of these complex disorders. Advances at the bench have been transformed to the bedside, and survival statistics reveal steady improvements. Nonetheless, although the survival rates may give reason to rejoice, the high early morbidity and persistent neurodevelopmental problems remain cause for concern. Such problems include bronchopulmonary dysplasia, nosocomial infections, necrotizing enterocolitis, hypoxic-ischemic encephalopathy, cerebral palsy, and the inability to sustain the intrauterine rate of growth when the infants are born prematurely. These problems need to be addressed in addition to the complex birth defects and genetic disorders that now loom as major problems in the neonatal intensive care unit.

The field of Neonatal Perinatal Medicine has transformed from anecdotal medicine to evidence-based medicine. The problem is that evidence-based medicine predicts outcomes for groups but not individuals. The next frontier, individualized, or personalized medicine, requires application of the human genome project to the individual patient. That frontier is gaining momentum amidst a dizzying proliferation of newly acquired scientific knowledge. The translation of bench research to bedside innovation is proceeding smoothly as is the understanding of the underlying mechanisms of many disorders. Advances in genetics have helped solve the etiology of many disorders, and many previously mysterious diseases can now be attributed to mitochondrial disorders accompanied by cellular energy failure. We have also attempted to address these advances.

With the combination of print and electronic journals, the effort to stay current in a single subspecialty remains a daunting task. Indeed, presenting the current status of the field of neonatal-perinatal medicine, even in a two-volume textbook, has become extremely challenging. It is a tribute to the contributors to *Neonatal-Perinatal Medicine* that this text has reached its ninth edition. We are profoundly grateful to both our loyal and our new contributors who give so freely of their time and knowledge.

For this ninth edition, we have added several new sections ranging from problems of the late preterm infant to fetal origins of adult disease. We have, in addition, completely reorganized and rewritten a large number of chapters and significantly updated the rest. Our accomplished authors and careful editing continue to focus on the biologic basis of developmental disorders and evidence basis for their management. We have also increasingly sought to draw upon international leaders in the field of neonatal-perinatal medicine to provide a truly global perspective.

This book would not exist without the remarkable clinical and intellectual environment that constitutes Rainbow Babies and Children's Hospital in Cleveland. On a daily basis, we gain knowledge from our faculty colleagues and fellows, and wisdom from our nursing staff, who are so committed to their young patients. Once again, we have been blessed with an in-house editor, Bonnie Siner, to whom we cannot adequately express our thanks. She is the glue behind the binding in the book and has worked tirelessly with Elsevier staff members to bring this project to fruition. Elsevier has once again provided the resources to accomplish this mammoth task.

SECTION I

The Field of Neonatal-Perinatal Medicine

From Infant Hatcheries to Intensive Care:

Highlights of the Century of Neonatal Medicine

Tonse N. K. Raju

> *We trust we have been forgiven for coining the words, "neonatology" and "neonatologist." We do not recall ever having seen them in print. The one designates the art and science of diagnosis and treatment of disorders of the newborn infant, the other the physician whose primary concern lies in the specialty. . . . We are not advocating now that a new subspecialty be lopped from pediatrics . . . yet such a subdivision . . . [has] as much merit as does pediatric hematology.*
>
> — *A. J. Schaffer, 1960*[71]

The American Board of Pediatrics offered the first examination in the neonatal-perinatal medicine subspecialty in 1975. By 2007, 4428 men and women were formally certified as neonatologists by the Board—a number more than the combined total of certified specialists in Pediatric Hematology and Oncology (2051), and Pediatric Cardiology (2016). The 1950 *Index Medicus* listed 218 publications that year under the subject heading "Infant, Newborn." By 1967, the number had increased to 6365, and in 2008, more than 400,000 publications were listed in *PubMed,* the National Library of Medicine's electronic database.[59] Dr. Schaffer need not have apologized for his visionary understatement—the specialty and the physicians he christened proved him prophetic. Although it was not "lopped" from pediatrics, this final frontier carved a niche, bridging obstetrics with pediatrics and intensive care with primary care.

The formal creation of neonatology may appear to be recent, but its roots extend into the 19th century, when systematic and organized care for premature infants began in earnest. This chapter traces the origins and growth of modern perinatal and neonatal medicine, with a brief perspective on its promises and failures. The reader may consult scholarly monographs and review articles on specific topics for in-depth analyses.[6,7,24,31,73,74]

PERINATAL PIONEERS

Many scientists played key roles in developing the basic concepts in neonatal-perinatal medicine that helped to formalize the scientific basis for neonatal clinical care. Their work and teachings inspired generations of further researchers advancing the field. For brevity's sake, only a few are shown in Figure 1-1.

Medicinal chemistry (later called biochemistry) and classic physiology gained popularity and acceptance toward the end of the 19th century, inaugurating studies on biochemical and physiologic problems in the fetus and the newborn. Some leading scientists in the early 20th century making fundamental contributions and training scores of scientists from around world included Barcroft[8,34] and his mentee Dawes in England (gas exchange and nutritional transfer across the placenta and oxygen carrying in fetal and adult hemoglobin); Ylppö in Finland (neonatal nutrition, jaundice, and thermoregulation); Lind in Sweden (circulatory physiology); Smith in Boston[76] (fetal and neonatal respiratory physiology); DeLee in Chicago[26,27] (leading researcher on incubators and in high-risk obstetric topics, he also founded the first U.S. "incubator station" at the Chicago Lying-in Hospital); Day in New York (temperature regulation, retinopathy of prematurity, and jaundice); and Gordon[38] in Denver (nutrition). Although the list appears long, the centers were scattered in location. Although it was not formal, the training

was nevertheless rigorous. Smith once said, "If you were interested in babies and liked Boston, I was the only wheel in town!"[60] Table 1-1 highlights some milestones in perinatal medicine.

HIGH-RISK FETUS AND PERINATAL OBSTETRICS

Because so many deaths occurred in early infancy in times past, many cultures adopted remarkably innovative methods to deal with such tragedies. According to a Jewish tradition, full, year-long mourning is not required for infants who die before 30 days of age.[40] In some Asian ethnic groups, infant-naming ceremonies are held only after several months, until which time the infant is simply called "it." In India, an odd or coarse-sounding name is given to the first surviving infant after the death of a previous sibling; this is aimed at deflecting evil spirits. In her book on the history of the Middle Ages, Tuchman notes that infants were seldom depicted in medieval artworks.[84] When they were drawn (e.g., the infant Jesus), women in the pictures looked away from the infant, ostensibly conveying respect, but perhaps because of fearful aloofness.

Since antiquity, the care of pregnant women has been the purview of midwives, grandmothers, and experienced female elders in the community. Wet nurses helped when mothers were unavailable or unwilling to nurse their infants. Little or no assistance was needed for normal or uncomplicated labor and delivery. For complicated deliveries, male physicians had to be summoned, but they could do little because many of them lacked expertise or interest in treating women. Disasters during labor and delivery were common, rendering this phase in their lives the most dreaded for women.[43] In the early 1900s, unexpected intrapartum complications accounted for 50% to 70% of all maternal deaths in England and Wales.[17,56] Because the immediate concern during most high-risk deliveries was saving the mother, sick newborns were not given substantial attention; their death rates remained very high.

Occasionally, happy outcomes of high-risk deliveries did occur. In one of the oldest works of art depicting labor and delivery (Fig. 1-2A), a bearded man and his assistant are standing behind a woman in labor, holding devices remarkably similar to the modern obstetric forceps. The midwife has delivered an evidently live infant. In Figure 1-2B, three infants from a set of quadruplets, nicely swaddled, have been placed on the mother, as the unwrapped fourth infant is being handed to her for nursing. A divine figure in the background is blessing the newcomers.

Cesarean sections were seldom performed on living women before the 13th century. Even subsequently, the procedure was performed only as a final act of desperation. Contrary to popular belief, Julius Caesar's birth was not likely by cesarean section. Because Caesar's mother was alive during his reign, historians believe that she probably delivered him vaginally. The term *cesarean* probably originated from *lex caesarea,* in turn from *lex regia,* the "royal law" prohibiting

TABLE 1–1 Selected Milestones in Perinatal Medicine

Category	Year(s)	Description
Antenatal aspects	1752	Queen Charlotte's Hospital, the world's first maternity hospital, is founded in London[57]
	1915-1924	Campbell introduces outlines of regular prenatal visits, which become a standard
	1923-1925	Estrogen and progesterone are discovered
	1928	First pregnancy test is described, in which women's urine is shown to cause changes in mouse ovaries
Fetal assessment	1543	Vesalius observes fetal breathing movements in pigs
	1634	Paré teaches that absence of movement suggests a dead fetus
	1819, 1821	Laënnec introduces the stethoscope in 1819, and his friend Kergaradec shows that fetal heart sounds can be heard using it
	1866	Forceps are recommended when there is "weakening of the fetal heart rate"
	1903	Einthoven publishes his work on the EKG
	1906	The first recording of fetal heart EKG is made
	1908	The term *fetal distress* is introduced
	1948-1953	There are developments in the external tocodynamometer
	1953	Apgar describes her scoring system[3]
	1957-1963	Systematic studies are conducted on fetal heart rate monitoring
	1970	Dawes reports studies on breathing movement in fetal lambs
	1980	Fetal Doppler studies begin
	1981	Nelson and Ellenberg report that Apgar scores are poor predictors of neurologic outcome
Labor and delivery	ca. 1000-500 BC	In Ayurveda, the ancient Hindu medical system, physicians describe obstetric instruments
	98-138	Soranus develops the birthing stool and other instruments
	1500s	There are isolated reports of cesarean sections on living women
	1610	The first intentional cesarean section is documented
	1700s	The Chamberlen forceps are kept as a family secret for three generations
	1921	Lower uterine segment cesarean section is reported
	1953	The modern vacuum extractor is introduced
Fetal physiology	1900-1950	Barcroft, Dawes, Lind, Liley, and others study physiologic principles of placental gas exchange and fetal circulation

EKG, electrocardiogram.
See references 2, 41, 43, 61, 78 for primary citations.

burial of corpses of pregnant women without removal of their fetuses.[11,89] The procedure allowed for baptism (or a similar blessing) if the child was alive or burial otherwise. Infants surviving the ordeal of cesarean birth were assumed to possess special powers, as supposedly did Shakespeare's Macduff—"not of a woman born," but of a corpse, and able to slay Macbeth.[54]

Soranus of Ephesus (circa 38-138 AD) influenced obstetric practice for 1400 years. His *Gynecology* can be regarded as the first formal "textbook" of perinatal medicine. Initially extant, it was rediscovered in 1870 and translated into English for the first time in 1956.[83] Soranus wrote superbly about podalic version, obstructed labor, multiple gestations, fetal malformations, and numerous other maternal and fetal disorders. In an age of belief in magic and the occult, he insisted that midwives should be educated and free from superstitions. He forbade wet nurses from drinking alcohol lest it render the infant "excessively sleepy." His chapter, "How to Recognize the Newborn That Is Worth Rearing," remains one of the earliest accounts on assessing viability of sick newborns—a topic of great concern even today.

MIDWIVES AND PERINATAL CARE

Although occasionally caricatured (Fig. 1-3), midwives were responsible for delivering obstetric care for thousands of years. Men disliked obstetrics, and women were shy to let male physicians handle them. Good midwives were always in

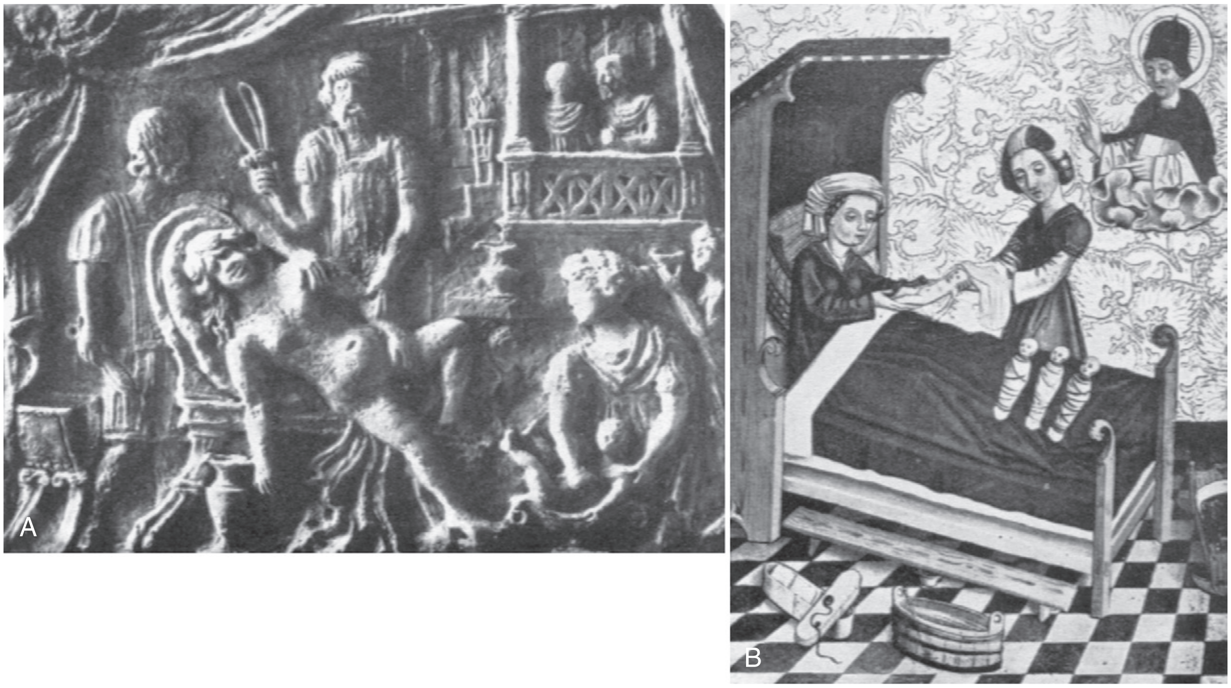

Figure 1–2. High-risk deliveries. **A**, Marble relief of uncertain date depicting a high-risk delivery. The physician and his assistant in the background are holding devices similar to modern obstetric forceps. A midwife has just helped deliver a live infant while two people are looking through the window. **B**, Delivery of quadruplets. *(From Graham H:* Eternal Eve: the history of gynecology and obstetrics, *New York, 1951, Doubleday, pp 68, 172.)*

great demand, and many of them held important social and political positions in European courts.[43,61,86]

The emergence of man-midwives (Fig. 1-4) in England had a major effect on high-risk obstetric practice. Chamberlen the Elder (1575-1628) is usually credited for inventing the modern obstetric forceps.[43,61,63] For 150 years, the instrument remained a trade secret through three generations of Chamberlens. By then, others had developed similar devices, and patients began associating good obstetric outcomes with male physicians—a key factor in transforming midwifery to a male-dominated craft.[43] The shift from women-midwifery to men-midwifery might also have been due to changing social values and gender relationships in which women voluntarily began making choices about their bodies.[86] Today’s increasing roles for female midwives and the higher proportion of women choosing specific birth practices (e.g., home versus hospital delivery, “underwater births,” cesarean delivery on request) offer interesting contrasts and perspectives to 18th century obstetrics.

NEONATAL RESUSCITATION: TALES OF HEROISM AND DESPERATION

Popular artworks and ancient medical writings provide accounts of miraculous revivals of apparently dead adults and children.[66] These are tales of successes only, for the failures were buried and rarely reported. Attempts to “stimulate” and revive apparently dead newborns included beating, shaking, yelling, fumigating, dipping in ice-cold water, and dilating and blowing smoke into the rectum.[25,30,66] Oxygen administration

through an orogastric tube to revive asphyxiated infants persisted well into the mid-1950s, when James and Apgar showed conclusively that the therapy was useless.[1,52]

APGAR AND THE LANGUAGE OF ASPHYXIA

Few scientists in the 20th century influenced the practice of neonatal resuscitation as profoundly as Apgar (1909-1974). A surgeon, she chose obstetric anesthesia for her career. Her simple scoring system inaugurated the modern era of assessing infants at birth on the basis of simple clinical examination.[3] Right or wrong, the Apgar score became the language of asphyxia. It is often said that the first words heard by a newborn infant are, "What's the Apgar score?" Although "giving an Apgar" has become a ritual, its profound effect has been on formalizing the process of observing, assessing, and communicating the infant status at birth in a consistent and uniform manner. This process eventually led to the formal steps of resuscitation at birth using the score. Few people know that it was also Apgar who was the first to catheterize the umbilical artery in a newborn.[16] A woman of enormous energy, talent, and compassion, Apgar was honored with her depiction on a 1994 U.S. postage stamp (Fig. 1-5).

FOUNDLING ASYLUMS AND INFANT CARE

In its early days, the Roman Empire experienced decreasing population growth. The emperors taxed bachelors and rewarded married couples to encourage procreation.[76] In 315 AD, Emperor Constantine, hoping to curb infanticide and encourage adopting of orphans, decreed that all "foundlings" would become slaves of those who adopted them. Similar humanitarian efforts by kings and the Council of the Roman Church led to the institutionalization of infant care by establishing foundling asylums for abandoned infants,[77] also called "Hospitals for the Innocent,"—the first children's hospitals. Parents of unwanted infants "dropped off" their infants in a revolving receptacle at the door of such asylums, rang the doorbells, and disappeared into the night (Fig. 1-6). Such accounts are poignant reminders of the contemporary problem of child abandonment because of which many states have programs to save such "dumpster babies," or the abandoned infants.[69]

Foundling asylums adopted pragmatic techniques for fundraising. In 18th century France, lotteries were held, and souvenirs were sold. In May 1749, Handel gave a concert to support London's "Hospital for the Maintenance and Education of Exposed and Deserted Young Children." The final item of the program was the playing of "The Foundling Hymn."[77]

SAVING INFANTS TO MAN THE ARMY

During the French Revolution, France faced appalling rates of infant mortality. With rates greater than 50%, the Revolutionary Council in 1789 enacted a decree, proclaiming that working-class parents "have a right to the nation's succors at all times."[77] The postrevolutionary euphoria about equality and fraternity among men stimulated reforms, heralding an idealistic welfare state, leading to collecting and maintaining valid statistics about children. The world's first national databases began in France in the late 18th century.[77]

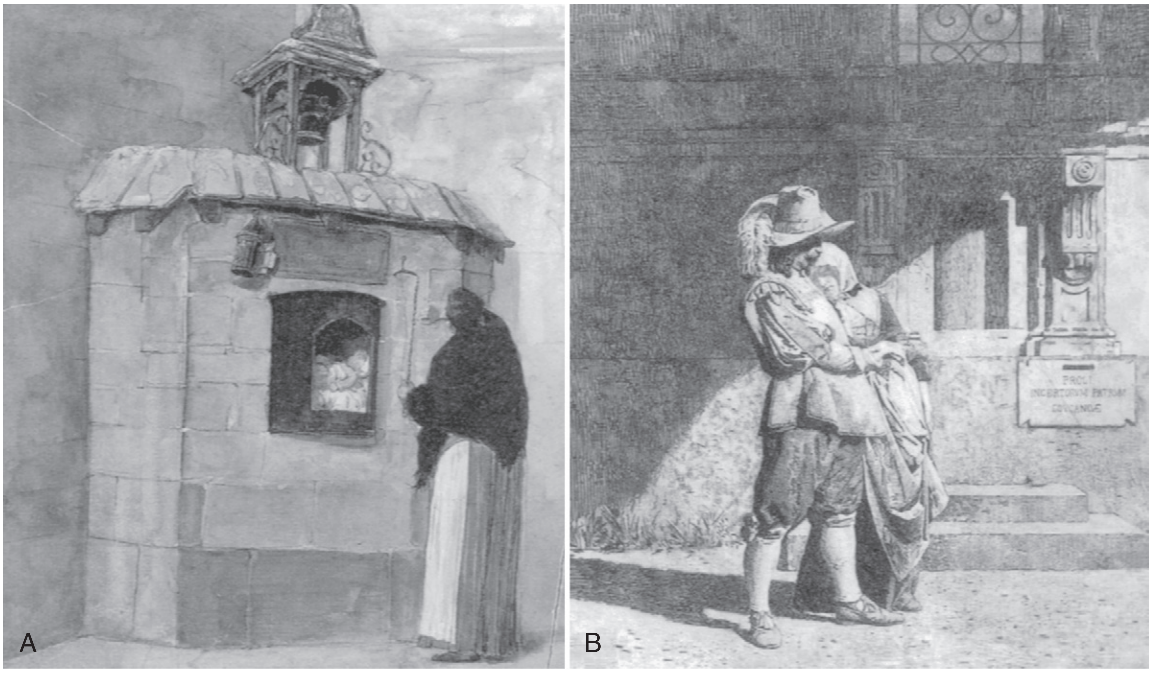

Figure 1–6. Foundling homes. **A**, *Le Tour*—revolving receptacle. Mother ringing a bell to notify those within that she is leaving her baby in the foundling home (watercolor by Herman Vogel, France, 1889). **B**, *Remorce* ("Remorse")—parents after placing their infant in a foundling home (engraving and etching by Alberto Maso Gilli, France, 1875). (**A** *and* **B**, *Courtesy of the Museum of the History of Medicine, Academy of Medicine, Toronto, Ontario, Canada; from Spaulding M, Welch P:*Nurturing yesterday's child: a portrayal of the Drake collection of pediatric history, *Philadelphia, 1991, Decker, p 110 [***A***] and p 119 [***B***].)*

Over the next century, France faced a population problem similar to that of ancient Rome—a negative population growth. The birthrate had declined, and infant mortality remained high. Fearing future shortages of troops, the military leaders, deeply engaged in battles with Prussia, were naturally alarmed. Commissions were set up to study the depopulation problem and develop remedial actions. A series of measures began to improve maternal and neonatal care.[6,7,22,24,77] Young parents were encouraged to uphold their patriotism and bear more children to "man the future armies." It is the irony of our times that such noble intentions as saving infants were motivated by brutal needs for enhancing military might.

AN INGENIOUS CONTRIVANCE, THE *COUVEUSE,* AND PREMATURE BABY STATIONS

A popular story of the origin of modern incubator technology is that on seeing the poultry section during a casual visit to the Paris Zoo in 1878, Tarnier (1828-1897), a renowned obstetrician, conceived the idea of "incubators" similar to the "brooding hen" or *couveuse*.[6,7,22,24] He asked an instrument maker, Martin, to construct similar equipment for infants. With a "thermo-syphon" method to heat the outside with an alcohol lamp, Martin devised a sufficiently ventilated, 1 m^3, double-walled metal cage, spacious enough to hold two premature infants. The first *couveuses* were installed at the Paris Maternity Hospital in 1880. Tarnier's efforts led to dramatic improvements in survival rates for preterm infants.

Although a few others had developed incubators before Tarnier,[7] it was he and his students, Budin (1846-1907) and Auvard, who are largely responsible for institutionalizing preterm infant care. They placed several incubators side by side, promoting the concept of caring for groups of sick preterm infants in geographically separate regions within their hospital.[6,7,81] Budin and Auvard improved the original *couveuse* by replacing its walls with glass and using simpler methods for heating. Their efforts greatly influenced incubator technology during the first half of the 20th century in Europe and the United States (Fig. 1-7 and Table 1-2).

In 1884, Tarnier made another important contribution; he invented a small, flexible rubber tube for introduction through the mouth into the stomach of preterm infants. With this tube, he could drip milk directly into the stomach. This method of nutritional support he called "gavage feeding." Gavage feeding plus keeping infants in relatively constant and warm temperatures had a dramatic impact on improving survival rates.[15,21] Tarnier also recommended that the legal definition of viability should be 180 days of gestation, which was opposed by contemporary obstetricians, who thought that the concept was "therapeutic nihilism."[7] Defining "viability" remains a highly emotional and contentious issue in contemporary neonatal/perinatal practice.

INCUBATORS, BABY SHOWS, AND ORIGINS OF NEONATAL INTENSIVE CARE UNITS.

Almost two decades after its debut in France, incubator technology appeared in the United States, heralding organized newborn intensive care. As in France, it was an obstetrician who spearheaded the movement. In 1898, DeLee established the first "Premature Baby Incubator Station" at the Sara Morris Hospital in Chicago. During the early 1900s,

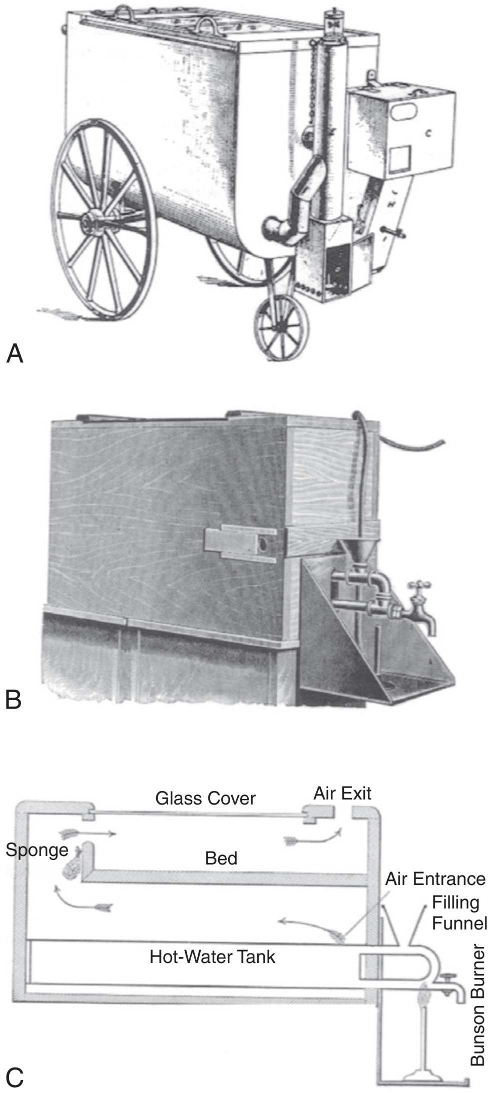

Figure 1–7. Early incubators. **A**, Rotch incubator, circa 1893. **B**, Holt incubator. **C**, Schematics of the Holt incubator. *(**A**, From Cone TE Jr:* History of American pediatrics, *Boston, 1979, Little Brown, pp 57 and 58, courtesy of Little Brown;**B** and **C**, From Holt LE:* The diseases of infants and children, *New York, 1897, Appleton, pp 12 and 13, courtesy of Appleton.)*

as academic obstetricians and pediatricians were organizing specialized care for premature infants, an interesting, if bizarre, set of events led to the era of “premature baby shows,” which began in Europe and continued in the United States, lasting well into the 1940s.[6,7,73,81]

Couney, a Budin associate of doubtful medical credentials, wished to popularize the French technology abroad and show the value of “conserving” premature infants. (This account has been doubted.[7]) Couney obtained six incubators, probably from the French innovator Lion. Initially, Couney wanted to exhibit only the incubators as a technology of hope for saving infants. To add drama, however, he brought six preterm infants from Virchow’s maternity unit in Berlin and exhibited them inside the incubators at the 1896 Berlin Exposition. He coined a catchy phrase for the show—*kinderbrutanstalt* or “child hatchery”—igniting the imagination of the public thirsty for sensational scientific breakthroughs.

Couney’s Berlin exhibit was an astounding success. He continued to organize similar baby shows and brought one of them to Great Britain’s Victorian Era Exhibition in 1897. An editorial in *Lancet* praised the show. It recommended that large “incubator stations” be established similar to fire stations, where parents could borrow incubators.[36] This was the origin of the phrase, “premature baby incubator stations,” which became part of the medical lexicon.

Couney set sail to the United States and organized the first U.S. incubator show in 1898 at the Omaha Trans-Mississippi Exposition. He settled in New York and established a permanent annual premature infant exhibit at New York’s Coney Island boardwalk that lasted for 40 years. Couney also took his premature infant shows during summer months to state fairs, traveling circuses, science expositions, and recreational expositions all over the United States (Fig. 1-8). The shows were particularly large in San Francisco, Chicago, St. Louis, Buffalo, and Minneapolis. About 8000 “Couney babies” were cared for in all of his exhibits. He claimed not to have charged any parent for the care. He made a lot of money—all from the entrance fee for his show—but he died poor. The last infant show was held during the 1939-1940 season in Atlantic City. A commemorative bronze plaque has been placed on the wall next to the entrance to the Holiday Inn Hotel, where Couney exhibits were held.[73]

The infant shows evoke familiar contemporary themes. The news media’s desire for obtaining spectacular stories of medical breakthroughs and the public’s curiosity about “rare phenomena” (e.g., quintuplet, sextuplet, or octuplet births) recall the memory of preterm infant show spectacles. The shows are also symbolic of the difficulty in preserving a delicate balance between information, public education and awareness, and sensationalism. Traveling infant shows were similar to traveling moon rock exhibits, which exploited the popularity of man’s landing on the moon and helped increase NASA’s annual budgets.

In 1914, Hess of Chicago started a Premature Infant Station at the Sarah Morris Children’s Hospital (of the Michael Reese Medical Center). With great attention to environmental control and aseptic practices and a regimental approach to feeding, Hess and his head nurse, Ms. Evelyn Lundeen (Fig. 1-9), achieved spectacular survival rates.[47,67] Hess also developed an incubator built on the concept of a double-walled metallic “cage” with warm water circulating between the walls. He used electric current for heating and devised a system to administer free-flow oxygen (Fig. 1-10). Only a few Hess incubators are known to have survived to this day. Hess’s premature unit outlasted the DeLee Premature Station. In December 2008, the Michael Reese Medical Center closed, however, declaring bankruptcy.

The story of development of incubators and their impact on pediatrics is a tale of the success of technology and that of the perils technology might beget (see later section on relationship of improved incubator care and the retinopathy of prematurity [ROP] epidemic). That incubators were able to save infants became a powerful symbol of the might of the machine. In the heroic age of the mechanical revolution, the notion that machines could solve all human problems was all too appealing. The incubator stands as the most enduring

TABLE 1–2 Evolution of Incubators

Year(s)	Developer/Product	Comments
1835, ca. 1850	von Ruehl (1769-1846)	A physician to Czarina Feodorovna, wife of Czar Paul I, von Ruehl develops the first known incubator for the Imperial Foundling Hospital in St. Petersburg. About 40 of these "warming tubs" are installed in the Moscow Foundling Hospital in 1850
1857	Denucé (1824-1889)	The first published account of introducing an incubator is a 400-word report by Denucé. This is a "double-walled" cradle
1880-1883	Tarnier (1828-1897)	Tarnier incubator is developed by Martin and installed in 1880 at the Port-Royal Maternité
1884	Credé (1819-1892)	Credé reports the results of 647 infants treated over 20 years using an incubator similar to that of Denucé
1887	Bartlett	Bartlett reads a paper on a "warming-crib" based on Tarnier's concept, but uses a "thermo-syphon"
1893	Budin (1846-1907)	Budin popularizes the Tarnier incubator and establishes the world's first "special care unit for premature infants" at Maternité and Clinique Tarnier in Paris
1893	Rotch (1849-1914)	The first American incubator with a built-in scale, wheels, and fresh-air delivery system is developed; the equipment is very expensive and elaborate
1897	Holt Incubator	A simplified version of the Rotch incubator is developed. In this double-walled wooden box, hot water circulates between the walls
1897-1920s	Brown, Lyons, DeLee, Allin	Many modifications are made to the early American and European incubators by physicians. These are called baby-tents, baby boxes, warming beds, and other names
1922	Hess	Hess introduces his famous incubator with an electric heating system. For transportation, he develops special boxes that can be plugged into the cigarette lighters in Chicago's taxicabs
1930-1950s	Large-scale commercial incubators	There is worldwide distribution of Air Shields and other commercial ventilators
1970-1980	Modern incubators	Transport incubators with built-in ventilators and monitoring equipment are developed—mobile intensive care units

See references 6, 7, 22-24, 73-75 for primary citations.

symbol of the spectacular success of modern intensive care and (paradoxically) some of its failures.[74,75]

SUPPORTIVE CARE AND OXYGEN THERAPY

In a single-page note in 1891, Bonnaire referred to Tarnier's use of oxygen in treating "debilitated" premature infants 2 years earlier[14]—this was the first published reference to the administration of supplemental oxygen in premature infants for a purpose other than resuscitation. The use of oxygen in premature infants did not become routine, however, until the 1920s. Initially, a mixture of oxygen and carbon dioxide—instead of oxygen alone—was employed to treat asphyxia-induced narcosis. It was argued that oxygen relieved hypoxia, whereas carbon dioxide stimulated the respiratory center.[80] Oxygen alone was reserved for "pure asphyxia" (whatever that meant). The advent of mobile oxygen tanks and their easy availability in the mid-1940s enabled the use of oxygen for resuscitation.[51,53,74]

The success of incubator care brought new and unexpected challenges.[68] Innovative methods had to be developed to feed the increasing number of premature infants who were surviving for longer periods than ever before. Their growth needed to be monitored, and illnesses related to prematurity, such as sepsis, apnea, anemia, jaundice, and respiratory distress, had to be studied and treated. Another completely unexpected peril from "improved" incubator technology was the epidemic of blindness from ROP (then called retrolental fibroplasia), documented in vivid detail elsewhere.[74,75] The apparent culprit in cases of ROP was the "leak proof" incubator that led to a great increase in the inspired oxygen concentrations (piped in free-flow manner), coupled with the belief that oxygen was innocuous, and if a little bit could save lives, a lot could save even more lives.[74,75] Because more and more sick and small preterm infants began surviving with incubator care, providing ventilatory assistance became an urgent necessity.

VENTILATORY CARE: "EXTENDED RESUSCITATION"

The first mechanical instrument used for intermittent positive pressure ventilation in newborns was the *aerophore pulmonaire*, a simple device developed by the French obstetrician

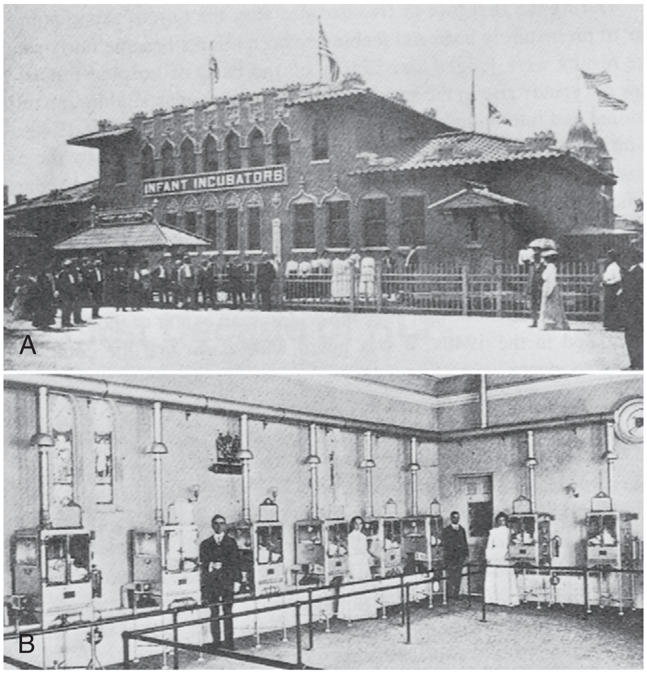

Figure 1–8. Incubator baby shows. **A**, People lined up to see the Infant Incubator Show, Buffalo, New York. **B**, Interior of an incubator baby show, Buffalo, New York. (**A** *and* **B**, *From Silverman WA: Incubator-baby side shows,* Pediatrics *64:127, 1979, courtesy of the American Academy of Pediatrics, 1979.)*

Gairal.[65,66] It was a rubber bulb attached to a J-shaped tube. By placing the bent end of the tube into the infant's upper airway, one could pump air into the lungs. Holt recommended its use for resuscitation in his influential 1897 book.[48]

Before starting mechanical ventilation, one needed to cannulate the airway, a task nearly impossible without a laryngoscope and an endotracheal tube. Blundell (1790-1878), a Scottish obstetrician, was the first to use a mechanical device for tracheal intubation in living newborns.[13,32] Introducing two fingers of his left hand over the infant's tongue, he would feel the epiglottis and then guide a silver pipe into the trachea with his right hand. His tracheal pipe had a blunt distal end and two side holes. By blowing air into the tube about 30 times a minute until the heartbeat began, Blundell saved hundreds of infants with birth asphyxia and infants with laryngeal diphtheria. His method of tracheal intubation is practiced in

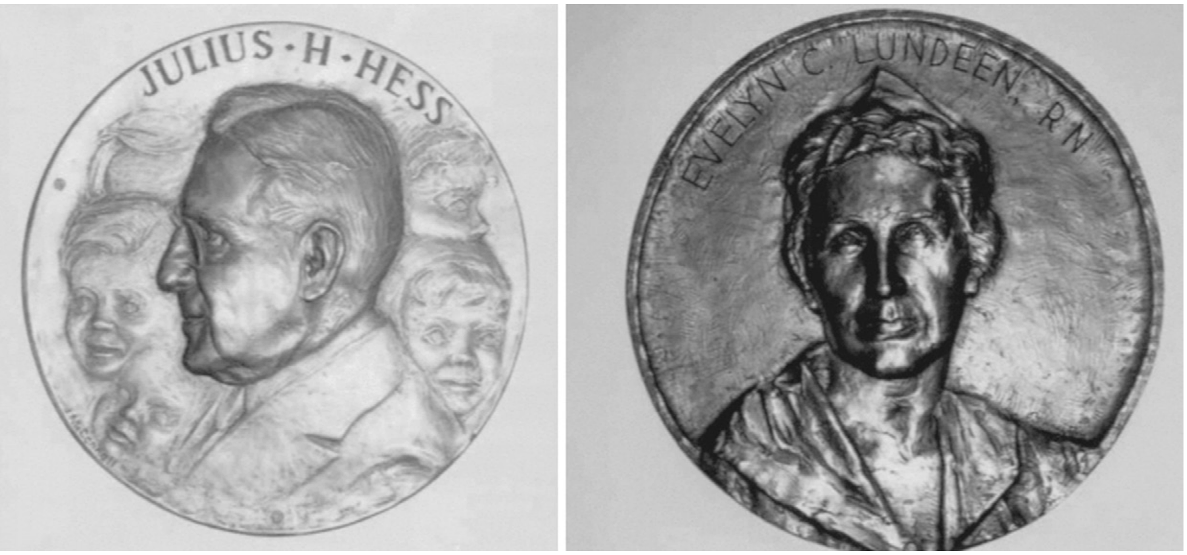

Figure 1–9. Hess and Lundeen medallions at the Michael Reese Hospital, Chicago. *(Photo courtesy of Tonse N. K. Raju.)*

many countries today.[85] In the late 19th century, a wide array of instruments evolved to provide longer periods of augmented or extended ventilation for infants who had been resuscitated in the labor room. Most of the early instruments were designed for use in adults, however, and were used later in newborns and infants, particularly to treat paralytic polio and laryngeal diphtheria.[39,45,79,80]

The iron lung (or "man-can") was one of the earliest mechanical ventilatory devices (Fig. 1-11), and a U.S. patent was issued for it in 1876.[19,20,42] In other ventilatory equipment, varying methods for rhythmic inflation and deflation of the lungs were used for prolonged ventilation. Among those, the Fell-O'Dwyer apparatus used a unique foot-operated bellows system connected to an implement similar to the aerophore bulb.[25,65,66]

Between 1930 and 1950, there were sporadic but important reports of prolonged assisted ventilation provided to newborns.[12,62,79,80] Beginning in the late 1950s and through the 1960s, more neonatal intensive care units (NICUs) began providing ventilatory assistance regularly (Table 1-3). Ventilatory care did not become predictably successful, however, until the early 1970s, when continuous positive pressure was incorporated into ventilatory devices.[44,58,62,79]

SUPPORTIVE CARE: INTRAVENOUS FLUID AND BLOOD TRANSFUSIONS

When it comes to intravenous therapy, our legacy is one of bloodletting, not of transfusing. Blundel (of intubation fame) also made a major contribution to transfusion science. Believing that "only human blood should be employed for humans," he developed instruments, syringes, and funnels for this purpose. In 1818, Blundel carried out the first direct transfusion from a healthy donor into a recipient; 5 of his first 10 patients survived.

Human-to-human transfusions gradually became accepted, but physicians in the 19th century were puzzled about unexpected disasters among blood transfusion recipients. It took 15 years after Landsteiner's discovery of blood groups in 1901 for the general acceptance and understanding of the scientific basis for blood group incompatibility.[87]

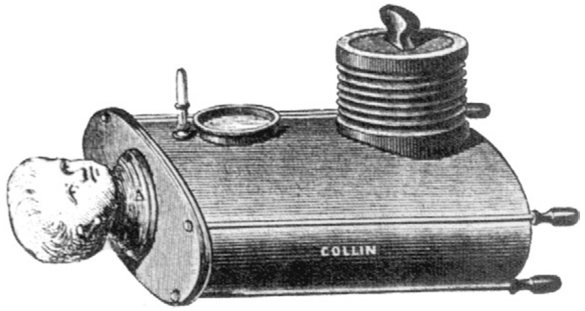

Figure 1–11. The Man-Can, circa 1873 to 1875. A hand-held negative-pressure ventilatory device for which a patent was applied in 1876.[19,20] *(From DeBono E:* Eureka: how and when the greatest inventions were made: an illustrated history of inventions from the wheel to the computer, *New York, 1974, Holt, Rinehart & Winston, p 159.)*

Adult transfusions were rare, but newborn transfusions were rarer still. On March 8, 1908, a 4-day-old term infant who had hemorrhagic disease of the newborn made history. "As the child's skin became waxen white and mucous membranes without color, it was decided to attempt transfusion of blood obtained from the infant's father," wrote Lambert from New York.[55] Carrel, a surgeon from Rockefeller University Hospital, performed an end-to-end anastomosis of the right popliteal vein of the infant with the left radial artery of the father. No anesthetic was given to either patient. "The amount of blood transfused could not be measured, but enough blood was allowed to flow into the baby to change her color from pale transparent whiteness to brilliant red . . . [and] as soon as the wound was sutured, the infant fed ravenously and immediately went to sleep," according to Lambert. Incidentally, Carrel was the first surgeon to develop innovative methods of suturing blood vessels—a contribution for which he received the 1912 Nobel Prize.

Despite Lambert's dramatic report, direct father-to-infant transfusion did not become routine. Because of unexpected reactions among the recipients, blood transfusions continued to be risky, despite proper matching of the donors' blood for major blood types. The mystery was understood only after the discovery of Rh subtypes by Landsteiner and Wiener in 1940.[87,90]

The discovery of the Rh blood types, leading to the conquest of erythroblastosis fetalis, remains an unparalleled triumph in pediatric medicine. This is an example of an orderly progression of accumulating knowledge leading to the near-eradication of a disease. First, there were the clinical descriptions of a disease (erythroblastosis); then there was a revolutionary, if symptomatic, therapy for it (exchange transfusion); and then there were efforts to prevent it (RhoGAM). The enthralling story of the conquest of erythroblastosis has been described superbly in many monographs and comprehensive review articles.[28,29,87,90]

TOOLS AND SUPPLIES FOR NEONATAL INTENSIVE CARE UNITS

It may be impossible for us to realize the hardship of performing such simple and mundane chores as the collection of blood from or insertion of catheters into the veins of preterm infants before the advent of ultra-small needles, pumps, and tubing. These were not available until the 1930s. In 1912, Blackfan (1883-1941) developed an ingenious suction device for blood collection.[9] Obtaining blood was done by puncturing the sagittal sinus or femoral or carotid veins; the latter sometimes led to accidental puncture of the nearby arteries. Well into the early 1970s, only a handful of laboratories could perform arterial blood gas analyses with less than 5 mL of blood.

Using the intraperitoneal route for treating dehydration or hypovolemic shock was common. Electrolyte solutions and blood were being administered directly into the peritoneal cavity with the expectation that its large absorptive surface allowed for rapid absorption.[10,91] In 1923, Sidbury introduced umbilical venous catheterization for neonatal blood transfusions,[72] and in the 1950s, Diamond and colleagues began using this route for exchange transfusions.[28,29] Indwelling polyethylene tubes were not introduced for gastric feeding until 1951.[70]

TABLE 1–3 Ventilatory Care, Respiratory Disorders, and Intensive Care

Category	Approximate Time Span	Procedures and Techniques
Resuscitation and oxygen	From antiquity to early 1970s	Mouth-to-mouth breathing (although it fell from favor in the late 18th century because many influential physicians declared it a "vulgar method" of revival)
	1878	Tarnier uses oxygen in debilitated premature infants
	1900-1930s	Schultz, Sylvester, and Laborde methods of resuscitation involve various forms of swinging infants (Schultz), traction of the tongue (Sylvester), and compression of the chest (Laborde)
	1930-1960s	Oxygen administration to the oral cavity through a rubber catheter
	1930s-1940s	Tight-fitting tracheal tube and direct tracheal oxygen administration
	1913-1920s	Byrd-Dew method: immersion in warm water, with alternate flexing and extending of the pelvis to help the "lungs open"
	1850-1930s	Dilation of the rectum
	1930-1950s	Inhalation of oxygen and 7% CO_2 mixture (for morphine-induced narcosis)
	1940-1950s	Positive-pressure air-lock (Bloxsom method)
	1940 to late 1950s	Concept that "air in the digestive tract is good for survival" is promoted—administration of oxygen to the stomach
	1950 to late 1960s	Hyperbaric oxygen in Vickers pressure chamber
	1950-1960s	Mouth-to-mouth or mouth-to-endotracheal tube breathing
Assisted ventilation	1930s-1980s	Bell develops a negative-pressure jacket
	1930-1950	Negative-pressure ventilators and iron lungs, used rarely in infants
	1960s	Positive-pressure respirators used for prolonged ventilatory support
	1971	Continuous positive airway pressure introduced for use in newborns
	1973	Intermittent mandatory ventilator
	1970-1980s	High-frequency ventilators; continuous monitoring of pulmonary function
Surfactant	1903	Hochheim reports "hyaline membranes" noted in the lungs of infants with RDS
	1940-1950s	Clinical descriptions and pathology studied
	1955-1956	Pattle discovers surfactant in pulmonary edema foam and lung extracts
	1959	Avery and Mead show absence of surfactant in infants with hyaline membrane disease[4]
	1971	Gluck introduces lecithin/sphingomyelin ratio
	1973	Liggins suggests that antenatal steroids help mature the pulmonary surfactant system
	1980	First effective clinical trial of postnatal surfactant therapy (bovine, Fujiwara)
	1989-1991	Commercial surfactants become available
	1995	Widespread antenatal steroid use leads to declines in rates for RDS and improves survival rates for infants with birthweight <1000 g, heralding a new era of epidemics of bronchopulmonary dysplasia and retinopathy of prematurity
Education research and patient care	1950 and beyond	Era of controlled clinical trials in neonatal medicine begins
	1970s	Regionalization of neonatal perinatal care
	1990s	Evidence-based medicine, systematic reviews
		Large perinatal networks for research (self-funded and federally funded)
	2005	Hypothermia for perinatal hypoxic-ischemic encephalopathy

PEDIATRIC SURGERY—NOT FOR RABBITS ANYMORE

As the trend of specialization among surgical subspecialties became popular, generalist surgeons resisted the change. Churchill, a famous surgeon, once remarked that his surgical residents at Massachusetts General Hospital "were quite proficient at operating on rabbits," and there was no need for a subspecialty in pediatric surgery.[35] Despite those objections, Harvard Medical School founded the first department of pediatric surgery in 1941 and named Ladd as its chair. Ladd and his pupils (among others) went on to show that pediatric and neonatal surgery was not the same as operating on rabbits.

GLOBAL NEONATAL CARE

By the middle of the 20th century, scores of neonatal units based on the Hess model were built in many European countries (Fig. 1-12) and the United Kingdom.[33,61] During the final decades of the 20th century, in many Asian countries, indigenous instruments and devices were being developed to improve neonatal resuscitation and intensive care for sick newborns. The impact of these developments on global neonatal and infant outcomes has yet to be assessed.

CONTROLLED CLINICAL TRIALS, EVIDENCE-BASED MEDICINE, AND RESEARCH NETWORKS

The modern era of controlled clinical trials evolved in the second half of the 20th century. The first randomized controlled clinical trial (RCT) in the United States was on a neonatal topic.[74,75] In 1949, in their newly established "infant station" at the Babies Hospital, New York, Silverman and colleagues saw an infant with a severe stage of ROP. This 1200-g infant was the son of a biochemistry professor. Desperate to do "anything" to prevent the infant becoming totally blind, Silverman's group decided to administer adrenocorticotropic hormone (ACTH). The infant made a dramatic recovery. This gave them the inspiration to "try" to design a placebo-controlled randomized trial using ACTH for ROP.

The results were disappointing. In addition to causing steroid-related side effects, ACTH was no more effective than the placebo in reducing ROP severity. The experience of organizing this trial led Silverman to develop additional RCTs in neonatal medicine, however, the most famous of which is the multicenter trial of curtailed or liberal use of oxygen to prevent ROP.[74,75]

With RCT as the backbone, advances in statistical methods and computer sciences gave rise to the science of systematic analyses, culminating in the founding of Cochrane Collaboration in 1993, named after the British epidemiologist Cochrane. The Collaboration produces and disseminates systematic reviews on therapies in all of medicine. It has more recently added assessment of accuracy of test results to its review topics. Among the 51 Cochrane review groups, the Pregnancy and Childbirth and the Neonatal Review groups have produced the largest number of systematic reviews.

Another welcome trend of the 1980s was the development of cooperative clinical and research networks. Examples of these include the self-funded Vermont Oxford Network and the federally funded Maternal Fetal Medicine Units and the Neonatal Research Network. Such cooperative networks have also been organized in the United Kingdom and European countries. These networks have conducted many highly successful collaborative clinical trials. With common protocols and shared resources, they have managed to enroll and study large numbers of research subjects within short time spans. The generic database maintained in these networks has become an invaluable resource for observational research. From the perspective of a historian, however, the long-term impact of these developments on the neonatal practice at the community (or practitioner) level and their overall impact on neonatal outcome need to be studied systematically.

SOME FAMOUS HIGH-RISK INFANTS

Shakespeare's King Henry VI offers one of the most poignant musings on the burdens of disability and the difficult birth (owing to footling presentation) of his brother, the Duke of Gloucester, who later became Richard III. Henry says to the Duke,[54] who was supposedly born premature (not confirmed by other historians), "Thy mother felt more than a mother's pain, yet brought forth less than a mother's hope." King Richard himself in a different Shakespeare play bemoans his misfortune[54]: "Deformed, unfinish'd, sent before my times/Into this breathing world scarce half made up."

Did King Richard have hemiplegic cerebral palsy as a consequence of prematurity? We cannot be sure. The list of leaders, celebrities, and famous individuals supposed to have been regarded as being at high risk at birth (Table 1-4) is impressive,[64] although the authenticity of the stories is difficult to confirm because most of them were derived from anecdotal statements.

TABLE 1–4 Ominous Beginnings for Some Famous Personalities

Category	Name	Description*
Religious	Moses	Jewish tradition holds that Moses was born "6 months and 1 day" after he was conceived; thus he could be hidden for 3 months from Pharoah's soldiers who were looking to find and kill the liberator of Jews[50,60]
Historical personalities and characters	Duke of Gloucester (later Richard III) (1452-1485)	Footling presentation, possibly premature; might have had cerebral palsy (hemiplegia?)[54]
	Macduff (Scottish nobleman in Shakespeare's *Macbeth*)	Delivered by cesarean section after his mother's death—"not of a woman born," but of a corpse[54]
Artists and writers	Jonathan Swift (1667-1745)	Mentioned by Cone[24]
	Licetus Fortunio (1577-1657)	"A fetus no more than five and one-half inches" at birth
	Pablo Picasso (1881-1973)	Left on the table as a stillbirth; his uncle, Don Salvador, a physician, resuscitated him
	Voltaire (1694-1778)	Premature and asphyxiated, the "puny little boy" was not expected to live and was hurriedly baptized; he was raised in the attic to keep him warm
	Samuel Johnson (1709-1784)	A huge baby, he was "strangely inert" at birth, required slapping and shaking. With persuasion, he made a few whimpers and lived
	Johann Wolfgang von Goethe (1749-1823)	After 3 days of labor, his mother delivered him; he was "lifeless and miserable" and thought to be stillborn at birth
	Anna Pavlova (1882-1931)	"A premature, so puny and weak," she was wrapped in cotton wool for 3 months
	Thomas Hardy (1840-1928)	He was thrown aside as dead at birth. "A good slapping" from the midwife revived him
	Sidney Poitier (born 1927)	Being 3 months premature, he was so small that his father "could place him in a shoebox." His grandmother said that despite prematurity, he would "walk with the kings." He did, when he became Bahamian ambassador to Japan in the 1990s[†]
Scientists	Johannes Kepler (1571-1630)	A "seven-month" baby; estimated IQ, 161
	Christopher Wren (1632-1723)	Mentioned by Cone[24]
	Isaac Newton (1642-1727)	Thought to be "as good as dead" at birth. He was such a "tiny mite" that he could be placed in a quart mug
Politicians	Franklin D. Roosevelt (1882-1945)	Weighed 10 lb at birth, but was "blue and limp with a deathlike respiratory standstill" from too much chloroform given to his mother, Sara Roosevelt
	Winston Churchill (1874-1965)	His early birth "upset the ball." Later a duchess remarked that the baby had such a lusty "earth-shaking" cry as she had ever heard. Recent historians doubt his premature birth

*The biographical notes are derived mostly from anecdotal statements of historians or family members or are from later recollection by the individuals themselves; we cannot be certain of the scientific validity of these stories.

[†] Quoted by Sidney Poitier in the television show *Biography*, CNN, Spring 2000.

FUTURE OF NEONATAL RESEARCH, EDUCATION, AND DATABASES IN THE INTERNET ERA

Of all the advances in the 20th century, none has made a greater impact on our lives than computers, the Internet, and information technology. The Internet and information technology opened new avenues for dissemination of research information and helped the development of clinical research databases. These resources need to give way for creative means pooling our collective experiences in patient care in a prospective manner.

Although today's NICU is a technological marvel, conceptually it remains a miniaturized version of the adult intensive care unit. Knowledge about the environmental influences on growth and development may change the shape of future NICUs. While the immediate and long-term adverse effects of excessive noise, light, handling, and pain on infant growth are being studied, attempts are being made to transform the impersonal intensive care environment into an infant-friendly experience. Many ultramodern NICUs have now been built on the concepts of environmental care. Such "kind and gentle" NICUs may be what Tarnier, Budin, Hess, and others conceived of some 100 years ago.

Despite incredible advances in the care of premature infants, today's scientists are facing many unresolved issues, including limits of viability, cost of care, quality of life for intensive care "graduates" (into their adult lives), and an ever-increasing battle against opportunistic nosocomial microorganisms.[74,75] A major concern is the definition of border of viability and the ethics of providing intensive or palliative care for infants born between 22 and 25 weeks' gestation. To the long list of new problems, one might add the growing realization that many adult-onset disorders may have developmental origins.

These and similar concerns also vexed the early pioneers of our subspecialty. Future historians may assess this century of neonatal medicine with the same sense of surprised wonder and awe that we now feel when remembering the days of infant hatcheries and baby incubator shows.

ACKNOWLEDGMENTS

CHAPTER 2

Epidemiology and Perinatal Services

PART 1

Epidemiology

Michele C. Walsh and Avroy A. Fanaroff

OVERVIEW

The neonatal-perinatal period is a time when the mother and fetus experience a period of rapid growth and development. At birth, the fetus makes an abrupt transition from the protective environment of the uterus to the outside world; the newborn infant must undergo extreme physiologic changes to survive this transition. The highest risk of infant death occurs during the first 24 hours after birth. Increased rates of mortality and morbidity continue during the neonatal period—from birth to the 28th day of life.

Mortality and morbidity rates are high early in life because the fetus and infant are vulnerable to numerous metabolic, genetic, physiologic, social, economic, and environmental injuries. These factors influence the gestation, delivery, and neonatal period, and have a major impact on the health of the fetus and infant.

The high incidence of mortality and morbidity during the perinatal period, which starts at the 28th week of pregnancy and extends to the 28th day after birth, makes it important to identify as early as possible mothers, fetuses, and infants who are at greatest risk. Of equal importance is the need to reduce the risk of morbidity, especially for handicapping conditions such as mental retardation. There is increasing evidence that early recognition of women with high-risk pregnancies and of high-risk infants followed by appropriate prenatal, intrapartum, and postpartum care can reduce the incidence of handicapping conditions and reduce the incidence of infant mortality.

Death of an infant is a source of anguish and grief to the parents and relatives. Infants who survive with disabilities and disease must endure personal suffering and may be a continuing source of pain, anguish, and loss of resources for their parents and society.[3,7,8] They may also impose a biologic burden on future generations by increasing the frequency of maladaptive genes in the population. In addition to the human tragedy, the fiscal impact of these problems on society is estimated to be in the billions of dollars each year.

Infants who are born before term gestation have the greatest risk of dying during infancy and of morbidity during childhood.[5,6] Infants with low birthweight (LBW) (<2500 g) are 40 times more likely to die than infants with normal birthweight, and infants with very low birthweight (VLBW) (<1500 g) are 200 times more likely to die. Infants with LBW are at a much higher risk of being born with cerebral palsy, mental retardation, and other sensory and cognitive impairments compared with infants with normal birthweight. Surviving infants with LBW also have an increased incidence of disability for a broad range of conditions, including various neurodevelopmental handicaps, respiratory illness, and injuries acquired as a result of neonatal intensive care. These infants often have a diminished ability to adapt socially, psychologically, and physically to an increasingly complex environment. Box 2-1 lists the risk factors for high-risk pregnancies that are often associated with LBW.

Important antecedents of many adult diseases, such as coronary artery disease, chronic renal and liver disease, and obesity, may have roots in early childhood, which implies that there may be very early opportunities for the prevention of adult chronic diseases.[2] Further improvement in longevity and decreased morbidity are likely to result from a better understanding of the origins of adult disease in fetal life and infancy and from the prevention and early treatment of these diseases.

BOX 2–1 Factors Associated with High-Risk Pregnancy

ECONOMIC
- Poverty
- Unemployment
- No health insurance; insufficient health insurance
- Poor access to prenatal care

CULTURAL-BEHAVIORAL
- Low educational status
- Poor health care attitudes
- No or inadequate prenatal care
- Cigarette, alcohol, drug abuse
- Age <16 or >35 years
- Unmarried
- Short time between pregnancies
- Lack of support group (husband, family, religion)
- Stress (physical, psychological)
- African-American race
- Abusive partner

BIOLOGIC-GENETIC
- Previous infant with low birthweight
- Low maternal weight at mother's birth
- Low weight for height
- Poor weight gain during pregnancy
- Short stature
- Poor nutrition
- Inbreeding (autosomal recessive?)
- Intergenerational effects
- Hereditary diseases (inborn error of metabolism)

REPRODUCTIVE
- Previous cesarean section
- Previous infertility
- Prolonged gestation
- Prolonged labor
- Previous infant with cerebral palsy, mental retardation, birth trauma, congenital anomalies
- Abnormal lie (breech)
- Abruption
- Multiple gestation
- Premature rupture of membranes
- Infections (systemic, amniotic, extra-amniotic, cervical)
- Preeclampsia or eclampsia
- Uterine bleeding (abruptio placentae, placenta previa)
- Parity (0 or >5)
- Uterine or cervical anomalies
- Fetal disease
- Abnormal fetal growth
- Idiopathic premature labor
- Iatrogenic prematurity
- High or low levels of maternal serum α-fetoprotein

MEDICAL
- Diabetes mellitus
- Hypertension
- Congenital heart disease
- Autoimmune disease
- Sickle cell anemia
- TORCH infection
- Intercurrent surgery or trauma
- Sexually transmitted diseases
- Maternal hypercoagulable states

TORCH, toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.

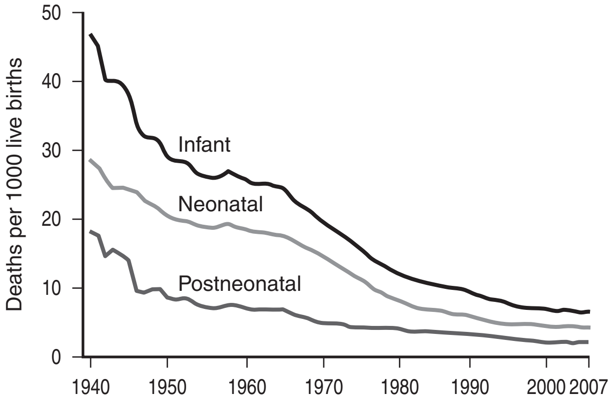
From Stoll JB, Kliegman RM: Section 1: noninfectious disorders. In Behrman RE et al, editors: *Nelson textbook of pediatrics,* 16th ed, Philadelphia, 2000, Saunders, p 461.

HIGH-RISK INFANTS

To decrease infant morbidity and mortality, pregnant women and infants at high risk should be identified as early as possible. Most high-risk infants can be identified before birth (see Box 2-1). Others are identified in the delivery room by abnormal growth status—small size for gestational age (weight <3% for gestational age) or large size for gestational age (weight >90% for gestational age)—or congenital malformation. Examination of a fresh placenta, cord, and membranes can alert the physician to a newborn at high risk.

Infant Mortality

Infant mortality is a critical measure of the health and welfare of a population.[5] In 2006, 4271 million infants were born in the United States, and 87,600 died before reaching age 1 year, resulting in an infant mortality rate of 6.7 deaths per 1000 live births. Rates of infant death in the United States have been declining steadily for at least 40 years and reached an all-time low in 2002 (Fig. 2-1).[5] Despite the constant improvement in national infant mortality rates, the United States ranks only



NOTE: Rates are infant (under 1 year), neonatal (under 28 days), and postneonatal (28 days–11 months) deaths per 1000 live births in specified group.

Figure 2–1. Infant mortality per 1000 live births in the United States, 1940-2005. *(From Kung HC et al: Deaths: final data for 2005,* Natl Vital Stat Rep *56:1-120, 2008, and from Jiaquan XU et al: Deaths: Preliminary Data for 2007,* Natl Vital Stat Rep *58:22, 2009.)*

25th in the world in infant mortality, well behind Sweden, Japan, Singapore, and Hong Kong.[5] Paradoxically, the birthweight-specific mortality in the United States is relatively low. That is, at each birthweight level, the infant mortality in the United States is very low. This low rate of birthweight-specific mortality is due to advances in neonatal care systems; most extremely tiny infants who may weigh 750 g at birth are now surviving.[1]

Most notable in the United States is the large disparity between African-American and white infant mortality. The mortality rate for African-American infants is more than double that for white infants (Fig. 2-2). In recent years, this ethnic and racial disparity has widened because the rate of decline in infant mortality has been higher among white infants than among African-American infants. Approximately half of all infant deaths were due to one of the four leading causes of infant death in 2005: congenital anomalies, short gestation and LBW, sudden infant death syndrome, and maternal complications of pregnancy.[4] Of the four leading causes of infant deaths, African-American infants are much more likely to die from being born too soon or too small and from maternal complications of pregnancy. National policymakers have developed the following strategies for eliminating the health disparity.

Infant deaths are divided into two categories according to age: neonatal (deaths of infants <28 days old) and postneonatal (deaths of infants between the ages of 28 days and 1 year). A decline in infant mortality rates was observed for neonatal deaths (4.8 per 1000) and postneonatal deaths (2.4 per 1000). Infant mortality numbers have declined by more than 40% since 1980. Neonatal death rates declined more steeply in the 1980s, and postneonatal death rates declined more steeply in the 1990s. Neonatal deaths are generally attributable to factors that occur during pregnancy, such as congenital malformations, low birth weight, maternal toxic exposures (smoking or other forms of drug abuse), and lack of appropriate medical care. In contrast, postneonatal deaths are generally associated with the infant's environmental circumstances, such as poverty, which often results in inadequate food, housing, sanitation, and medical care.

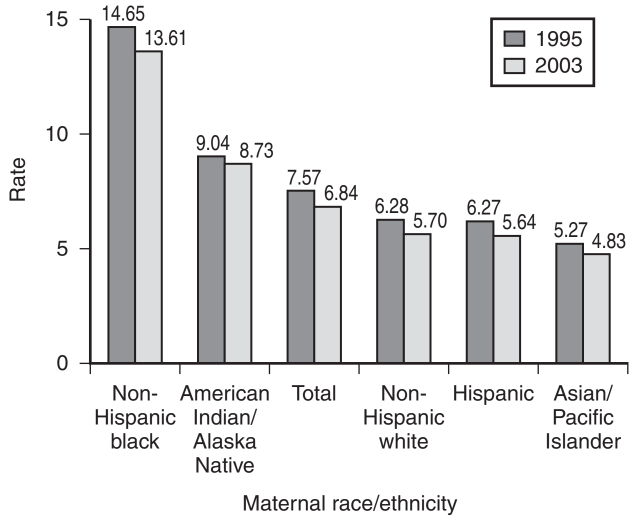


Figure 2–2. Disparities in infant mortality by race and ethnicity in the United States, 1995 versus 2003. (*From MacDorman MF et al: Fetal and perinatal mortality, United States, 2004,* Natl Vital Stat Rep *56:1-19, 2007.)*

The decline in neonatal deaths among infants with LBW in the 1990s may be because of increased survival in neonatal intensive care units (NICUs), healthier infants with LBW, or both. It is estimated that two thirds of the decline in severity-adjusted mortality was due to increased survival in neonatal intensive care, and that one third was due to healthier infants with LBW. Increased survival in neonatal intensive care is attributed to the more aggressive use of respiratory and cardiovascular treatments. The improved health of infants with LBW is attributed to improvements in obstetric and delivery room care.

Generally, for any given gestational age, the lower the infant birthweight, the higher the neonatal mortality; for any given birthweight, the younger the gestational age, the higher the neonatal mortality. Infant death rates decrease steeply with increasing infant birthweight. The lowest risk of infant death occurs among infants with birthweights of 3000 to 4000 g, and risk increases slightly for infants weighing more than 4000 g and for infants whose gestational age is older than 42 weeks.[6] Infants who survive past the first 28 days of life have a vastly better prognosis.

Infant Morbidity

PRETERM INFANTS, INFANTS WITH LOW BIRTHWEIGHT, AND INFANTS WHO ARE SMALL FOR GESTATIONAL AGE

Live-born infants born before 37 completed weeks of gestation (<259 days after the date of the mother's last menstrual period) are defined as preterm (Fig. 2-3). Measures of live-born infant size include LBW (infants weighing <2500 g) and two subgroups of LBW, moderately LBW (infants weighing 1500 to 2499 g) and VLBW (infants weighing <1500 g). Other measures take into consideration gestational age and birthweight, such as small for gestational age, defined as live-born infants weighing less than the 10th percentile for gestational age; appropriate for gestational age, defined as infants weighing between the 10th and the 90th percentiles for gestational age; and large for gestational age, defined as infants weighing more than the 90th percentile for gestational age.

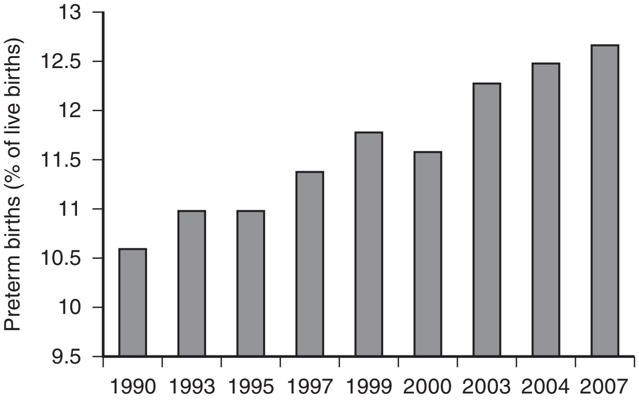

Figure 2–3. Preterm births in the United States by year expressed as percentage of total live births. (*Redrawn from National Center for Vital Health Statistics, Rep 56, 2007 and* Natl Vital Stat Rep *57:14, 2009.)*

The health of an infant with LBW is directly related to gestational age. An infant weighing 1800 g born at term is very different from an infant weighing 1800 g born at 32 weeks. An infant weighing 1800 g born at term is defined as having LBW and being small for gestational age, but an infant weighing 1800 g born at 32 weeks is defined as having LBW, being preterm, and being appropriate for gestational age. Two infants each weighing 1800 g of unequal gestational ages would require very different care (see Chapter 14). Infants with extremely low birth weight (ELBW) (weighing <1000 g) have the greatest risk of death and neurodevelopmental impairment. Tyson and colleagues[10] at the National Institute of Child Health and Human Development Neonatal Research Network developed an evidence-based calculator to inform physicians and families of the predicted risks for individual infants with ELBW born between 22 and 25 weeks using not only gestational age, but also exposure to antenatal steroids, sex, and multiple births. The calculator can be accessed at http://www.nichd.nih.gov/about/org/cdbpm/pp/prog%5Fepbo/.

In the United States today, infants with LBW account for a relatively greater proportion of infant deaths than in the past. Early in the 20th century, two thirds of infant deaths occurred in the postneonatal period, primarily from infectious diseases. By 1950, 7.5% of live-born infants weighed less than 2500 g, and two thirds of all infant deaths occurred in the neonatal period. The causes of these deaths were related to antenatal and intrapartum events, such as birth injury, asphyxia, congenital malformations, and "immaturity." Advances in the development of perinatal care in the 1950s and 1960s came as a result of the awareness of the increased morbidity in surviving infants with LBW coupled with a greater understanding of fetal and infant nutrition, pharmacology, and pathophysiology.

The infant mortality rate decreased 47% from 1965 to 1980, primarily because of the increased survival of high-risk infants with LBW. Regionalization of neonatal intensive care has brought perinatal intensive care to most families in need and has contributed significantly to the increase in the fraction of infants with LBW and VLBW who are cared for in tertiary centers. Decreased rates of neonatal mortality also were observed after the introduction of regionalized care (see Part 2). Despite these impressive gains, the U.S. international ranking in infant mortality has continued to decline compared with other countries.[6] In 1960, the United States ranked 12th in infant mortality; by 1990, the United States ranked 23rd; and by 2004, the United States ranked 29th, tied with Poland and Slovakia.

In 2005, 36.5% of all infant deaths in the United States were due to a preterm-related cause of death. In addition, there has been an increase in the percentage of infants born preterm. Prematurity constitutes a major health problem. Surviving infants with LBW also remained three times as likely as infants of normal birthweight to have adverse neurologic sequelae. The risk of adverse sequelae increases with decreasing birthweight. Lower respiratory tract problems, particularly infections, are more common, as are complications of neonatal care.

The risk of giving birth to an infant with LBW is increased among African-American women, women who smoke during pregnancy, unmarried women, women with low educational attainment, women who have no or inadequate prenatal care, and women who have had a previous infant with LBW (see Box 2-1). There is a substantial and persistent difference between African-American and white infants in the risk of LBW and preterm delivery. African-American women are 2.4 times as likely to have an infant with LBW than white women and 2.6 times more likely than Chinese-American women. The higher LBW rate among African-American women has been observed for more than 20 years. African-American infants are more likely to die of preventable causes than white infants. In addition, African-American infants have significantly higher rates of mortality for every cause of infant death except congenital anomalies and sudden infant death syndrome. Infant mortality rates were also elevated for Puerto Rican and American Indian women.

Decades of research about the disparities in LBW rates and infant mortality between African-American and white infants have been unable to explain the racial disparities in birth outcomes. Scientists have studied the impact of education, maternal age, vaginal infection, exposure to cigarette smoke, use of alcohol, stress, socioeconomic status, and many other risk factors. None of these factors explain the racial disparities in death or LBW rates. Compounding the widening gap between African-American and white rates of LBW is the increasing number of women at high risk in the population. Increases during the 1980s in acquired immunodeficiency syndrome, poverty, use of illicit drugs such as crack cocaine, syphilis, and births to unmarried women are additional factors that are associated with further increases in infant mortality and LBW. Promising intervention strategies include modifying behaviors, lifestyles, and conditions that affect birth outcomes, such as smoking, substance abuse, poor nutrition, lack of prenatal care, medical problems, and chronic illness.

Conditions that make the uterus unable to retain the fetus, interference with the course of pregnancy, premature separation of the placenta, or a stimulus to produce uterine contractions before term are generally associated with preterm infants with an appropriate weight for gestational age. Medical conditions that interfere with the circulation and efficiency of the placenta, the development or growth of the fetus, or the general health and nutrition of the mother are associated with infants who are small for gestational age.

ALARMING INCREASES IN INFANTS WITH LOW BIRTHWEIGHT

In recent years, there has been alarming increase in the frequency of late preterm deliveries (see ch. 34) (defined as infants at 34 to <37 weeks' gestation). In part, the increase has been driven by parents and obstetricians who believe that neonatal morbidity at these gestations is equivalent to morbidity at term gestation. This perception is incorrect, however. Infants delivered by elective cesarean section at 38 weeks' gestation are 1.3 to 2.1 times more likely to have adverse respiratory outcomes and intensive care unit admission, whereas infants delivered at 37 weeks' gestation are 1.8 to 4.2 times as likely compared with infants delivered at 39 completed weeks of gestation (Fig. 2-4).[9] The frequency of delivery by cesarean section has increased in parallel with the increasing LBW deliveries; together, these have ominous implications for the health of these infants and for the cost of health care. The March of Dimes and other national organizations, including the American Academy of Pediatrics, have

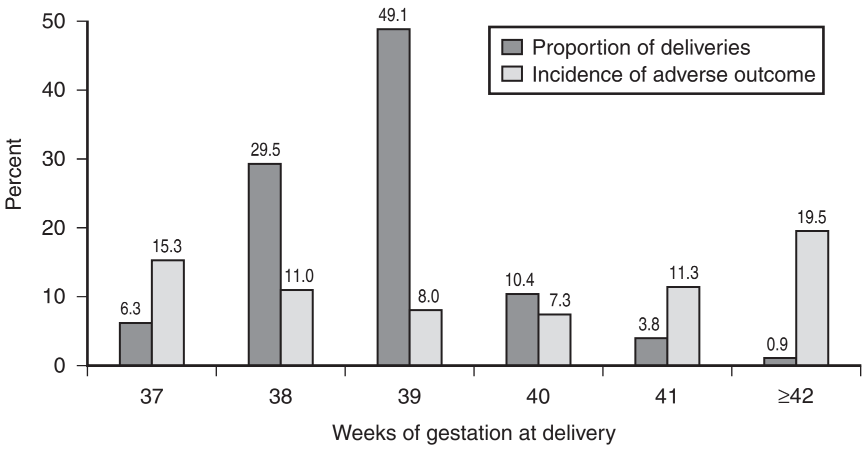

Figure 2–4. Elective repeat cesarean delivery (N = 13,258) and the incidence of adverse outcomes (composite of neonatal death and any of several adverse events, including respiratory complications, treated hypoglycemia, newborn sepsis, and admission to the neonatal intensive care unit) according to the number of completed weeks of gestation. *(From Tita AT et al: Timing of elective repeat cesarean delivery at term and neonatal outcomes,* N Engl J Med *360:111-120 2009.)*

begun campaigns to educate the public about these increased risks and to encourage delays in delivery until 39 completed weeks of gestation.

FUTURE PROGRESS

Prevention of Infant Mortality and Low Birthweight

Although all the precise causes of infant mortality and LBW are unknown, prevention efforts can make substantial progress toward decreasing infant mortality and LBW.[9,11] In the United States, much of the progress in reducing infant mortality has been a result of improvements in neonatal and perinatal care. As evidenced by the stable rates of LBW and preterm birth in the United States, there has been little or no progress to date in preventing LBW or preterm birth. Things can be done to prevent LBW, however. If smoking during pregnancy were eliminated, the infant mortality rate would decrease by 10%, and the LBW rate would decrease by 25%. Decreasing the incidence of unplanned pregnancies, decreasing the abuse of alcohol and illicit drugs, increasing enrollment in the Special Supplemental Food Program for Women, Infants, and Children (WIC), and providing prenatal care in a comprehensive and coordinated manner also could reduce infant mortality and LBW.

Preventing pediatric mortality and morbidity associated with LBW requires a broad range of activities that involve the family, health care professionals, and community groups. These activities include identifying prepregnancy risks; counseling for risk reduction; implementing school health programs; increasing early, high-quality prenatal care services; expanding the content of prenatal care to meet the variable needs of individual women and selected high-risk groups, and developing, implementing, and supporting a long-term public information program with a few well-chosen messages targeted at LBW risks (e.g., smoking cessation).

Fetal Development, Physiology, and Biochemistry

Improvements in our understanding of and ability to measure embryonic and fetal physiologic and biochemical homeostasis are likely to advance the practice of neonatal-perinatal medicine. In addition, as we increase understanding of the mechanisms controlling labor, of the protective circulatory adjustments of the fetus to hypoxia, and of pharmacology, we can develop new means to detect high-risk pregnancies successfully, treat the fetus, and prevent preterm labor.

Investigation of the cellular and molecular levels of development and pharmacology of the uterus, placenta, and fetus may be crucial to understanding the mechanisms that control labor. Such an understanding would enable physicians to decrease the incidence of preterm infants or infants with LBW. Prenatal diagnosis and biochemical and ultrasound fetal monitoring may be only the first steps toward the development of future treatments. These future treatments may include hybridization of cells in the early blastocyst or embryo to correct inborn errors of metabolism, stimulation of embryogenesis of organs, gene therapy, acceleration of organ maturation, and pharmacologic interventions to ameliorate hypoxic injury to the central nervous system.

Legal and Ethical Issues

Advances in the field of neonatal-perinatal medicine have focused attention on numerous legal and ethical issues. There is continuing concern about life-and-death decision making in NICUs. New and complex societal relationships among the physician, patient, family, and nursing staff exist in these units, and this development has had an enormous impact on the process of making medical decisions. As a result of regionalization, we now have nearly universal access to care in NICUs, and this broad access has brought these ethical issues into a sharper and more demanding focus.

Specific criteria must now be formulated for making decisions that previously were made on the basis of access to the health system, which was strongly influenced by the economic position of a family. Should a 500-g infant with a poor prognosis for intact survival be accepted to the NICU when it means one cannot accept a 2000-g infant who is at high risk but has a good prognosis if he or she survives, just because the referring physician in the case of the 500-g infant calls first, or because the 500-g infant is born in the same hospital where the intensive care unit is located?

Ironically, although not surprisingly, as the technology of care increases in these units, the difficult choices for the physician are not the technical medical decisions, but rather the matters of judgment that require evaluating the complex human interests of the relatives, their friends and advisors, and the staff, and the various consequences for the people involved. These decisions have always been the most challenging and demanding ones for physicians because they cannot be delegated to others. The new elements are the frequency and complexity of these judgments in regional neonatal intensive care centers (see Chapters 3 and 4).

Quality of Care

Whatever decision-making process is used to improve the quality of care, certain principles are important, but often not easy to apply. The fundamental responsibility of all concerned is to do no harm or, at least, no harm without a reasonable expectation of a compensating benefit for the patient. A corollary principle is that there must be continuous, scientific evaluation of the care provided and of proposed innovations. Clinicians should not initiate or continue activities that on balance do harm to the well-being of a newborn infant. The definition of *well-being* is a major problem because the varying ethical values, religious commitments, and life experiences of all the individuals who care for and about the infants and legal restraints must be taken into consideration. Generally, the minimal elements of well-being include a life prolonged beyond infancy, without excruciating pain and with the potential of participating in human experience to at least a minimal degree (see Chapter 5).

PART 2

Perinatal Services

Michele C. Walsh and Avroy A. Fanaroff

HISTORICAL PERSPECTIVE

Before 1940, perinatal care services were delivered in the United States, Canada, and Europe without any particular organization. Most of the care was provided by an individual physician or midwife. In many areas, most deliveries occurred in the home. Larger urban areas often had numerous maternity hospitals, usually serving as teaching hospitals, with home delivery services and neighborhood clinics serving a geographic area.

During the 1940s and early 1950s, many cities in the United States developed centers for the care of premature infants. Many European countries, particularly The Netherlands and the Scandinavian countries, developed systems of care for perinatal patients based on the development of primary prenatal care clinics staffed largely by midwives, with district and regional hospitals for the care of mothers with complications.

From 1964 to 1968, studies were undertaken in Massachusetts, Wisconsin, and Arizona to analyze the causes of neonatal mortality and morbidity.[4,8] These studies suggested that expert care of high-risk neonates could reduce infant mortality rates. In 1976, the March of Dimes Committee on Perinatal Health developed recommendations based on this research that supported a network of perinatal care providers that supplied care to a geographic region. The report, entitled “Toward Improving the Outcome of Pregnancy” (TIOP), spurred many states to regionalize care.[31]

By the end of the 1980s, 26 states had regionalized perinatal care, and studies documenting a shift in deliveries from level I to level II and level III centers emerged, together with data documenting reductions in neonatal mortality. Despite these data, in the early 1990s, state by state, the regionalized systems were weakened as factors put pressure on the system (Table 2-1). In 1993, the March of Dimes convened the second TIOP conference and reexamined the theory supporting regionalization.[7] The conference participants concluded that regionalization continued to be the best option for reducing perinatal morbidity.

TABLE 2–1 Factors Threatening Regionalized Perinatal Care

Physician Related	Institution Related
Oversupply and poor distribution of physicians	Use of high-tech procedures as a marketing tool
Desire to perform all services for which they were trained, regardless of level of care designated	Desire to perform all services to allow contractual arrangements with provider
Lack of incentive to improve care at other hospitals and potential decrease in patient referrals	Lack of incentive to improve care at other hospitals and potential decrease in patient referrals
Fear of loss of patients	Institutional ego
Failure to recognize problems warranting referral	

Modified from Institute of Medicine: *Prenatal care: reaching mothers, reaching infants,* Washington, DC, 1988, National Academy Press.

PRINCIPLES OF REGIONAL CARE

General principles that form the basis for the development of regional health care services for perinatal patients include organization by geographic region, accountability for outcomes, and one standard of quality across care sites.[1] A region denotes a geographic area or population with definable care needs. The regional center and the network of related institutions are accountable for the overall perinatal health care for the region. Data on mortality and morbidity, frequency of problems, and quality of care are assessed for the entire population in the area. The availability and quality of care in any given institution become the responsibility of all the institutions, including the perinatal center.

Regionalization is based on the premise that there should be a single standard of quality across sites of care. Every mother and infant should have equal access to all the components of a functioning perinatal system (Table 2-2). Institutions operating within a region differ in their ability to provide perinatal care. Each institution is expected to deliver high-quality care up to the level of its capability. When care requirements exceed the institution's capability, the patient is referred to the closest facility that has the required capability.

Of problems associated with increased risk for the mother, fetus, or newborn, 60% to 80% are detectable sufficiently in advance of the crisis either to permit the appropriate care resources to be made available locally or to transfer the patient to where appropriate resources are available.[14] Even under ideal circumstances, some patients must move from one facility to another during the course of care. Institutions within a region must be effectively linked to permit ease of patient movement. Subspecialty centers are charged with outreach education to expand the care of basic and specialty units in their region.

Regionalization permits optimal use of facilities and personnel. With a regional perinatal center, sufficient numbers of high-risk mothers and neonates are concentrated in a single location to justify economically the staffing and equipment necessary to meet care needs.[44] In addition, personnel who have frequent opportunities to use their skills are able to maintain and enhance these skills. Institutions with smaller numbers of high-risk patients avoid the expense of developing services that are infrequently used. The health care needs of perinatal patients require a close working relationship among the various disciplines involved to prevent fragmentation and gaps in care.

CURRENT RECOMMENDATIONS ON ORGANIZATION

Countries with better perinatal mortality and morbidity statistics have universal primary care for all pregnant women and have established mechanisms for referring mothers and infants from primary care institutions to district hospitals when needed. They have placed less emphasis on tertiary care because of the lower demand for such services. In contrast, perinatal health services of the United States and Canada place great emphasis on the specialized hospital services for perinatal patients, but primary care services available to mothers during pregnancy are disorganized and inconsistent. The number of perinatal patients requiring intensive in-hospital care is inversely related to the quality and availability of primary services and to the general health status of mothers before pregnancy.

An organized system for perinatal care begins with a well-integrated ambulatory care system that emphasizes early risk assessment. Prenatal care may be delivered by basic providers (family practice physicians or nurse practitioners), specialty providers (obstetricians or experienced family practitioners), or subspecialty providers (maternal-fetal medicine specialists) as appropriate to the level of risk. As the woman's risk status changes during pregnancy, so may the level of care needed. No care system is effective if it is not used. TIOP II emphasized that "early and continuous prenatal care is an important and effective means to improve the outcome of pregnancy."[7] In the 1980s, virtually no progress was made, however, in increasing the number of women receiving early prenatal care, and the number of women receiving late or no care increased. More work needs to be done to understand better the barriers to prenatal care.

The Institute of Medicine described the following six barriers to adequate prenatal care: financial problems, inadequate capacity in care systems used by low-income women, services that are difficult to navigate (unfriendly), lack of awareness and acceptance of unintended pregnancy, personal beliefs about prenatal care, and social isolation.[3,18] TIOP II proposed solutions to ameliorate each of these barriers (Table 2-3).[7] An organized system for providing care to a pregnant woman and her infant after birth consists of the following types of facilities: physicians' offices and clinics, basic perinatal facilities, specialty perinatal facilities, subspecialty perinatal facilities, regional perinatal centers, and specialized units such as children's hospitals and cardiac centers.

TABLE 2–3 Reducing Barriers to Prenatal Care through System Change

Barriers	Related COPH Recommendations
Financing	Health care coverage for all pregnant women
	Mechanisms to ensure adequate provider payment
Capacity	More efficient use of existing providers
	Improved linkages between public and private and ambulatory and inpatient providers
Lack of user-friendly services	Matching provider capabilities and expertise to individual need and risks
	Risk assessment to identify medical, personal, and cultural barriers
Unintended pregnancy	Reproductive awareness among all women
	Greater emphasis on preconception care and care during pregnancy, including family planning
Personal beliefs and attitudes	Health promotion and health education for all children
	Reproductive awareness among all women
Social isolation	Outreach programs

COPH, Committee on Perinatal Health.

Physicians' Offices and Clinics

The basic units for care during pregnancy and for care of the mother and infant after delivery are physicians' offices and general clinics. These units must be able to obtain a complete health history, careful physical assessment of the mother or infant, systematic risk assessment (using one of the available risk-scoring systems), and laboratory resources for determining hematocrit or hemoglobin concentration and urinalysis.

Basic Perinatal Facilities (Level I)

Basic perinatal facilities are designed primarily for the care of maternal and neonatal patients who have no complications. Because complications can arise in previously uncomplicated cases, basic units must have the resources to provide competent emergency services when the need arises. The necessary services for a basic perinatal facility are shown in Table 2-2 and include a normal newborn nursery. Capabilities for different levels of neonatal care are summarized in Table 2-4.

Specialty Perinatal Facilities (Level II)

Specialty perinatal facilities are hospitals that have larger maternity and newborn services. These hospitals are located in urban and suburban areas serving larger communities. In addition to providing a full range of maternal and newborn services for perinatal patients who have no complications, they provide services for obstetric and neonatal patients who have one or more complications. The range of obstetric and neonatal complications an institution can treat depends on its resources. The services available in specialty units are presented in Table 2-2 and include a normal newborn nursery and a transitional-care nursery. Care of high-risk neonates should be provided by appropriately qualified physicians. A board-certified pediatrician with special interest, experience, and in some situations subspecialty certification in neonatal-perinatal medicine, should be chief of the neonatal care services.

Subspecialty Perinatal Facilities (Level III)

In addition to the resources and capabilities of a specialty unit, subspecialty facilities can provide a full range of maternal complications and newborn intensive care. The neonatal intensive care unit (NICU) must have a full range of services for neonates, with the possible exception of infants with congenital heart disease or other complex congenital anomalies who require a specialized unit. The services offered by subspecialty facilities are listed in Table 2-2 and include intensive care for mothers and infants. The director of a subspecialty unit should be a full-time, board-certified pediatrician with subspecialty certification in neonatal-perinatal medicine.

Regional Perinatal Center

A regional perinatal center is a subspecialty facility that also is responsible for coordinating and managing special services, including transportation, that are needed for the region. In areas where there is only one subspecialty facility, the facility is expected to function as the regional perinatal center. In areas where there is more than one unit with subspecialty capabilities, one of the units would serve as the regional perinatal center. The regional perinatal center must offer outpatient and inpatient consultation and diagnostic services for basic and specialty facilities within the region, including ultrasonography, laboratory analysis of amniotic fluid, assessment of gestational age, genetic studies, and other studies of fetal health. It also should provide specialized nursing services and consultation in nutrition, social services, respiratory therapy, and laboratory and radiology services. The center is responsible for conducting an active outreach education program for the institutions, health professionals, and public within the region.

A regional perinatal center has unique personnel needs. It should be directed by a full-time physician with extensive training and experience in perinatal medicine and administration. There also should be a director of obstetric services and a director of neonatal services. The director of obstetric services should be a full-time physician with training and experience in fetal-maternal medicine, including maternal intensive care. The director of neonatal services should be a full-time neonatologist with training and experience in neonatal care, including newborn intensive care. The perinatal nursing services should be directed by a clinical nurse specialist with advanced experience in maternal and neonatal nursing and in administration. The center also may require a full-time director of the outreach education program to coordinate the active participation of physicians in obstetrics and newborn care, nurses in obstetrics and newborn care, nutritionists, social workers, and other specialized personnel. The obstetrics and newborn care units, including the newborn intensive care unit, should have clinical nurse specialists in obstetrics and neonatal care responsible for organizing the nursing program and coordinating the patient care needs.

It is important to estimate the number of pregnant women who might need specialized obstetric and neonatal services within the area of a given regional perinatal center. The percentage of pregnancies at increased risk may vary from 10% for general populations, such as an entire state or country, to more than 90% in some urban hospitals. In an Ontario, Canada, perinatal study, 32% of pregnancies had some increased risk factor that resulted in 60% of the neonatal problems. In the Nova Scotia Fetal Risk Project, 11% of 9483 patients accounted for 50% of the stillbirths and 75% of the neonatal deaths.

The number of neonatal intensive care beds and neonatal intensive care days needed for a given population are most influenced by the frequency of premature birth and low birthweight (LBW). There are great differences in these frequencies among countries and among populations within a country. Infants with LBW account for less than 5% of the births in the Scandinavian countries and 6% to 9% of infants in some states in the United States; in some institutions, the percentage may be 15% to 20%.[28]

Swyer and associates[39] calculated a need for neonatal intensive care beds at 0.7 beds per 1000 live births on the basis of a 7% LBW rate. Transitional or intermediate and convalescent bed needs were approximately 4 per 1000 live births. The Wisconsin Perinatal Care Program predicted a need for 12 intensive care beds for 6000 live births (7% LBW rate). Data from Utah indicate a need for 2 beds per 1000 annual live births in special care facilities. The estimated breakdown

TABLE 2–4 Proposed Uniform Definitions for Capabilities Associated with Highest Level of Neonatal Care within an Institution

Level I Neonatal Care (Basic)

- Well-newborn nursery: has the capabilities to
  - Provide neonatal resuscitation at every delivery
  - Evaluate and provide postnatal care to healthy newborns
  - Stabilize and provide care for infants born at 35-37 wk gestation who remain physiologically stable
  - Stabilize newborns who are ill and infants born at <35 wk gestation until transfer to a facility that can provide the appropriate level of neonatal care

Level II Neonatal Care (Specialty)

- Special care nursery: level II units are subdivided into 2 categories on the basis of their ability to provide assisted ventilation including continuous positive airway pressure
  - Level IIA: has the capabilities to
    - Resuscitate and stabilize preterm or ill infants before transfer to a facility at which newborn intensive care is provided
    - Provide care for infants born at >32 wk gestation and weighing ≥1500 g (1) who have physiologic immaturity such as apnea of prematurity, inability to maintain body temperature, or inability to take oral feedings or (2) who are moderately ill with problems that are anticipated to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis
    - Provide care for infants who are convalescing after intensive care
  - Level IIB has the capabilities of a level IIA nursery and the additional capability to provide mechanical ventilation for brief durations (<24 hr) or continuous positive airway pressure

Level III (Subspecialty) NICU

- Level III NICUs are subdivided into 3 categories
  - Level IIIA: has the capabilities to
    - Provide comprehensive care for infants born at >28 wk gestation and weighing >1000 g
    - Provide sustained life support limited to conventional mechanical ventilation
    - Perform minor surgical procedures such as placement of central venous catheter or inguinal hernia repair
  - Level IIIB NICU: has the capabilities to provide
    - Comprehensive care for extremely low birthweight infants (≤1000 g and ≤28 wk gestation)
    - Advanced respiratory support such as high-frequency ventilation and inhaled nitric oxide for as long as required
    - Prompt and on-site access to a full range of pediatric medical subspecialists
    - Advanced imaging, with interpretation on an urgent basis, including computed tomography, magnetic resonance imaging, and echocardiography
    - Pediatric surgical specialists and pediatric anesthesiologists on site or at a closely related institution to perform major surgery such as ligation of patent ductus arteriosus and repair of abdominal wall defects, necrotizing enterocolitis with bowel perforation, tracheoesophageal fistula or esophageal atresia, and myelomeningocele
  - Level IIIC NICU: has the capabilities of a level IIIB NICU and is located within an institution that has the capability to provide ECMO and surgical repair of complex congenital cardiac malformations that require cardiopulmonary bypass

ECMO, extracorporeal membrane oxygenation; NICU, neonatal intensive care unit.
From Stark AR, Couto J; American Academy of Pediatrics Committee on Fetus and Newborn: Levels of neonatal care, *Pediatrics* 114:1341, 2004.

was 0.5 level I beds, 0.5 level II beds, and 1 level III bed per 1000 annual live births.[20] In the United Kingdom, Field and colleagues[12] reported that the demand for neonatal intensive care was 1.1 beds per 1000 deliveries. This was a minimum estimate, and factors such as increased survival of extremely immature infants would increase the demand for beds.

REGIONALIZATION

Impact on Neonatal Morbidity and Mortality

Paneth and associates[27] analyzed all singleton births and deaths with known birthweight and gestational age in New York City from 1976 through 1978. Mortality rates for full-term, appropriately grown infants were not influenced by the hospital of birth. Preterm infants and infants with LBW were at a 24% higher risk of death, however, if birth occurred at either a level I or a level II unit. These small infants constituted only a small percentage of the births, but accounted for 70% of the deaths.[35]

Fanaroff's group compared the outcomes of neonates delivered between 24 and 28 weeks' gestation at National Institute of Child Health and Human Development network level III units with neonates of similar gestational age who were transported to the centers after birth.[10] Outborn infants had significantly more respiratory distress syndrome (88% versus 81%), more grade III or IV intraventricular hemorrhages (24% versus 17%; odds ratio 1.61, 1.12 to 2.16), and greater mortality (32% versus 22%; odds ratio 1.63, 1.15 to 2.30).

Yeast and colleagues[43] compared neonatal mortality in two 5-year periods (1982-1986 versus 1990-1994) in Missouri. They found that in both periods the relative risk of neonatal mortality in level II centers was 2.28 compared with level III centers, and that no substantial improvement had occurred in those 10 years. Similar data have been reported from California.[6,29] There are compelling reasons for preterm deliveries to occur at tertiary centers.

Maternal and Neonatal Transport Services

It is estimated that antenatal maternal transfer is impossible in 50% of high-risk pregnancies. In these situations, neonatal transport must be performed by specially trained teams skilled in adequate stabilization before and effective management during transport. Hood and associates[17] documented a 60% greater mortality rate when neonates were transferred by an untrained versus a trained neonatal transport team. Hypothermia and acidosis in particular were more common after transfer by an untrained team. National groups have recommended standards for personnel configuration, training, and accreditation.[42] The transport team from the referral hospital also serves an important educational function and can influence and improve methods of stabilization at the referring center, which may influence mortality statistics (see Chapter 5).

An effective means of managing overcrowding at a perinatal referral center is to encourage reverse transport of previously ill neonates to levels I and II nurseries for intermediate care.[19] Transfer can include not only infants with resolved acute medical problems, but also infants with chronic problems such as bronchopulmonary dysplasia. The tertiary center must be familiar, however, with the capabilities, facilities, and resources of the hospitals to which reverse transport is occurring so that quality of care can be ensured. This evaluation can be combined with an outreach education program. Apart from the cost-effectiveness of reverse transport, it can encourage family bonding and greater involvement of the pediatrician who will be offering continuing care to the infant.

The outcomes of infants transported back from tertiary centers to community hospitals (level II units staffed by skilled personnel) were compared with outcomes of infants convalescing in the tertiary center. Lynch and colleagues[24] documented that the transported infants received appropriate care, were less likely to need readmission to the intensive care unit (7% versus 14%), and required fewer transfusions. Major new health problems developed in 27% of the patients during convalescence. The overall complication rate was lower, however, for the reverse transfers. The current medical economic climate mandates that tertiary units establish criteria for reverse transfer, and many health maintenance organizations and preferred provider organizations are demanding early reverse transport. Tertiary units are obliged to ensure that there are appropriately trained personnel and adequate facilities at their community hospitals so as not to compromise the medical needs or care of the neonates requiring reverse transfer.

Problems

One of the most common problems of regionalization is centralization in place of regionalization; this is the end product of a regional center that operates with no outreach education program or other mechanisms for continuing the development and improvement of services in the other hospitals of the region. With such a system, the central hospital continues to receive the referrals of high-risk mothers or high-risk neonates, but makes no effort to help the referring hospital develop programs for preventing the problems. This may be particularly true in university medical centers, where outreach education and service are not considered a regular academic or hospital activity. This problem improved with increased use of reverse transports.[5] This progress is threatened, however, because some third-party and government payers refuse to reimburse the expense of the reverse transport, even when the result is to relocate care to a less expensive institution.

A second common problem of regionalization is unnecessary duplication of units[36]; this includes the unnecessary duplication of basic and specialty units within rural or urban areas and competing subspecialty units, particularly in urban areas. The duplication results in difficulties in recruiting and maintaining the necessary personnel for such care units and an increased cost per patient for such care. Such duplication invariably is a result of competing institutions and competing medical staffs, who view maternal intensive care and NICUs as important to their business, income, or institutional image.

Some regional centers are staffed with inadequate or inappropriately trained personnel. In the past, a common problem was the staffing of infant intensive care nurseries with inadequately supervised resident staff as the primary responsible physicians, particularly during night hours and weekends. Data indicate, however, that 23% to 75% of subspecialty centers have increasingly moved to 24-hour in-house specialty coverage by attending neonatologists.[9,36]

NECESSITY OF REGIONALIZATION OF PERINATAL CARE

In the 1970s, a spirit of cooperation drove the development of regionalized systems. The realities of health care reform, competition, and cost constraints have dimmed that cooperative spirit. More hospitals are merging and forming networks, which jointly contract with payers to supply complete health services to a population of "covered lives." These forces lead every network to wish to provide all levels of service in a given area so that covered lives stay within that system. This situation leads to duplication of services that runs counter to the principles of regionalization.[33]

The availability of a large supply of highly trained neonatologists, together with financial incentives, led to the creation of new levels of care termed *level IIB, level II plus,* or *community NICUs*.[26,38] The development of these centers shifted the location of high-risk births away from level III centers to community NICUs in California and other states.[16]

Gould and coworkers[15] evaluated the impact of this deregionalization on neonatal mortality and documented that by 1997 regional NICUs lost 5.2% of California's live births. Only 20% of the reduction occurred because of a shift of deliveries to community NICUs, however; 80% of the shift was to level I and level II (intermediate) NICUs. Neonatal mortality was similar at the regional NICUs and community NICUs, but remained elevated at intermediate NICUs (odds ratio 1.54), self-designated intermediate NICUs that were not certified by the state (odds ratio 1.33), and primary care units (odds ratio 1.56).

Cifuentes and coworkers,[6] also working with health statistics from California, similarly identified a mortality disadvantage for neonates with very LBW at level II NICUs and identified an impact of average daily census: centers with a census less than 15 had increased mortality. Rogowski and colleagues[34] were unable to confirm this association in the Vermont Oxford Network. Kamanth and associates[21] analyzed births in Colorado and showed decreased mortality risk among infants weighing less than 750 g born in a level III center versus those born in a non–level III center.

Financial Impact

The facilities within a regional network, including a regional perinatal center, financially depend on a combination of patient revenue and public support to care for neonatal patients. With carefully coordinated use of resources and facilities, the cost of care can be contained.[13,22,23,44] It is essential that health insurance programs provide adequate coverage for obstetric and neonatal conditions, and that charges reflect the cost of delivering the services.

Medical assistance and other forms of payment and direct support of state and county hospitals must be adequate for the care needs. There must be adequate nursing staff, physician coverage, equipment, and supplies to achieve an acceptable quality of care. The reimbursement schemes should provide for patient transfer between institutions without multiplication of deductibles or major financial hardship to the patient. The cost of emergency transport of high-risk maternal and newborn patients should be covered. Financial incentives should promote, rather than discourage, the use of resources appropriate to patient care needs.

Diagnosis-related grouping has been implemented as the basis for federal reimbursement, and other third-party payers have followed suit. The limited initial database used to determine the reimbursement level did not take into account many variables that influence length of stay, particularly at a tertiary center.[2,23,30] If the guidelines are not modified, major tertiary centers will be at a distinct financial disadvantage, particularly when providing care for extremely complicated problems and infants with LBW. The system could also discourage transport of infants from primary and specialty units if the referring hospitals perceive financial gain; the quality of care may be compromised.

MEASUREMENTS OF EFFECTIVENESS OF CARE ORGANIZATION

When the effectiveness of any care system and its individual components is measured, it is essential to analyze data for the entire region. A hospital can show dramatic changes in mortality or morbidity statistics in the course of a single year, not as a result of improvement of care, but as a result of movement of patients with particular problems to another institution. If the geographic boundaries of a region are well designed, there should be limited patient movement from region to region. This permits consistent year-to-year evaluation of the care within the region.

Maternal mortality has declined to the point that it is no longer a satisfactory index of quality of care in developed countries. Fetal and neonatal mortalities are still reasonable indicators of perinatal care.[11] In evaluating a region, the data must link the hospital in which the death is recorded with the institution and the community in which the birth occurred or the care was initiated. Fetal and neonatal mortalities should also be divided by weight groups. The weight groups should be in 500-g increments or less, beginning with 500 g. If possible, the gestational age distribution and cause of death for the fetal or neonatal deaths should be established.

Sex and transport status (maternal or neonatal) have been shown to affect mortality.[10,37] Such practices make it possible to identify areas or institutions within a region in which there are major problems with care. Any comparison of mortality is most useful if a risk adjustment tool is applied, such as the Clinical Risk Index for Babies (CRIB) or Score for Neonatal Acute Physiology (SNAP) (see Chapter 5).[32,40] Such scores correct for the inherent bias of subspecialty centers that receive only the sickest neonates and experience the highest mortality.

When maternal, fetal, or neonatal mortality and morbidity rates are used, certain other information is necessary to permit useful interpretation. For maternal mortalities, it is essential to separate the maternal deaths that occurred during or as a result of pregnancy associated with other maternal disease, such as severe cardiac disease or malignancy, from deaths associated primarily with the pregnancy. This separation requires analysis of each death and assignment to preventable or unpreventable categories. For evaluation of neonatal programs and regionalization, the frequency of 1-minute Apgar scores of 3 or less and 5-minute Apgar scores of 5 or less should be recorded. Also helpful in assessing effectiveness of care are the frequency of sepsis, traumatic delivery, respiratory distress syndrome, and neurologic problems; the number of intensive care days; and the number of patient transfers from community institutions to institutions of greater care capability.

All high-risk mothers and neonates should have systematic follow-up care. Infants with a birthweight of less than 1500 g are at high risk for developmental, neurologic, or learning problems, and should be followed into school age with careful neurologic and educational testing (see Chapter 41).[25,41] The incidence of child abuse and failure to thrive may also reflect parenting disorders having antecedents in the perinatal period.

FUTURE CONSIDERATIONS

Centers for newborn care have expanded at specialty (level II) institutions with large delivery services so that many have developed capabilities similar to those at subspecialty centers. In many geographic areas, the subspecialty and specialty units compete; in others, the two centers work hand in hand. In all communities, it is essential that mutually productive relationships be reestablished between the academic and community hospitals.

Most board-certified neonatologists in the United States now practice outside traditional academic settings. These personnel needs are being met by the university-based training programs. With fewer training programs accredited and more trainees completing a third fellowship year, however, it is conceivable that in the near future there will not be enough trained neonatologists to staff the ever-expanding specialty units. At present, the major strategies are to provide cost-effective medical care, to comply with regulations that dictate standards required for reimbursement, and, above all, to prevent LBW and prematurity.

CHAPTER 3

Medical Ethics in Neonatal Care

Jonathan Hellmann

This chapter explores the complexity of moral problem solving in neonatal medicine. First, principles of medical ethics and key terms and concepts are defined, followed by the application of these concepts in specific moral problems that arise (1) when a pregnant patient refuses treatment, (2) in the prenatal consultation at the limits of viability, and (3) when withholding and withdrawing life-sustaining medical treatment in the neonatal intensive care unit (NICU) is undertaken. A collaborative, procedural framework for consensual end-of-life decision making is described, and specific ethical issues that may arise in end-of-life care are discussed, including the use of analgesic agents, brain death and organ donation, palliative care, and the withdrawal or withholding of artificial nutrition and hydration. This chapter includes guidelines for ethical conflict resolution and an approach to the conduct of clinical research. Finally, a brief summary of ethical responsibilities of neonatal physicians is presented.

Three elements characterize the practice of medicine that are timeless, universal, and irrefutably true: (1) the *fact* of illness and the vulnerability it creates, (2) the *act* of the profession (the use of medical skills for the benefit of the patient), and (3) the *practice* of medicine itself—that which physicians and patients do together in the clinical encounter, characterized by mutual intentionality.[61] These three elements are well exemplified in the care of sick newborn infants, where the vulnerability of anxious parents is manifest, where the clinical competence and moral discretion of health professionals are used for the benefit of newborn patients and their parents, and where the practice is carried out in a patient-parent-physician relationship characterized by mutual trust and pursuit of the neonatal patient's and parents' good.

Medical ethics involves the systematic, reasoned evaluation and justification of the "right" action in pursuit of human good or well-being in the context of medical practice. It involves a critical examination of the concepts and assumptions underlying medical and moral decision making, and it may include a critical examination of the kind of person a physician should be.[61] Medical ethics has become a central focus in the practice of neonatal intensive care because it contains all the elements of moral discourse but without clear-cut, "right" answers. Numerous ethical issues arise as physicians attempt to determine what is right and good for their vulnerable patients, when physicians and parents deliberate on what constitutes the "best interests of the infant," and when NICUs use their technological capability in the quest for medical progress.

These issues are compounded by the fact that the treatment occurs in a fast-paced environment that precludes or severely limits opportunities for in-depth exploration of parents' and physicians' views and values. It is also complicated by the medical uncertainty surrounding accurate outcome prediction of potentially adverse findings, and the very nature of many decisions in which quality of life and life *itself* may be under consideration. All these issues make the NICU a challenging, highly scrutinized environment in how ethical issues are examined, reasoned, and justified, and raises fundamental questions about what the responsibilities of neonatal health care providers should be.

Ethical issues may be experienced as moral dilemmas, moral uncertainty, or moral distress. A *moral dilemma* is present when the physician believes there is an obligation to pursue two (or more) conflicting courses of action. As only one of these courses can be pursued, the physician has to make a value-based choice that compromises one of these obligations. A classic example in neonatal care is a conflict between action required by the principle of respect for autonomy and action required by the principle of beneficence.

Moral uncertainty typically arises when the presenting issue is unclear. Parents whose fetus has a major congenital anomaly are presented with the option of terminating that pregnancy or anticipating major surgery for their infant at the time of birth. They are unwilling to end the pregnancy, but are uncertain about the varying prognoses given to them by respective physicians. They, and possibly their care providers, remain unclear and uncertain about the principles and values that are in conflict.

Moral distress arises when the decision maker feels certain about the morally right thing to do, but this perceived "right" course of action is precluded for numerous reasons, including the caregiver's lack of decision-making authority or institutional or financial constraints. Neonatal nurses who have intense hands-on contact with newborns may feel powerless and experience moral distress when treatment decisions are made by others.[32] Ulrich and colleagues[74] have elucidated the feelings of powerlessness, frustration, and fatigue experienced by nurses and social workers in relation to ethical issues in their workplace. The number of surveys of neonatologists' preferences and practices at the limits of viability is also likely a reflection of a degree of moral distress within that group, as is the more personal, plaintive, and painful expression of the neonatal fellow in dealing with an infant "abandoned in the NICU" when faced with parental insistence on "doing everything" possible for a severely compromised and socially vulnerable infant.[10]

PRINCIPLES IN MEDICAL ETHICS

Ethical reasoning requires an understanding of the principles that define a domain (Box 3-1); the principles of autonomy, beneficence, nonmaleficence, and justice in the care of newborns are briefly discussed to suggest ways in which these principles can be interpreted. Although reference to principles serves as a useful checklist of moral concerns, appealing to principles per se in the clinical context can be of limited value when the problem revolves around a conflict in the principles themselves. In many cases, a "principlist" paradigm may not do justice to the nature or complexity of the moral problem. In addition, in a purely principle-based approach, the role of the neonatal health care provider as *moral agent* (i.e., someone with personal virtues and values and the opportunity to take action that comports with that judgment of morality) is not highlighted. This chapter does not prescribe adherence to any particular ethical theory, but aims to enhance appreciation of the language of ethical discourse to enable nuanced reflection, reasoning and ethical decision making, and to underline the role of the health care provider in these situations.

Autonomy

Autonomy grounds the right of competent patients to make their own health care choices. An individual who makes an autonomous choice acts intentionally, with understanding and without external controlling influences.[8] An idealized expression of respect for autonomy with *adult* patients is one in which mentally and emotionally capable patients choose voluntarily and intelligently from among various options whose relative risks and benefits have been fully explained to them by their physicians (i.e., via a truly informed consent process).

BOX 3–1 Key Concepts Underlying Ethical Care in the Neonatal Intensive Care Unit

- Respecting parental authority/autonomy
- Applying the best interests of the infant standard of judgment
- Minimizing harm to the newborn
- Developing sound parent-physician relationships
- Empowering and informing parents
- Applying family-centered care principles
- Respecting parents' values and cultural and religious beliefs
- Sharing decision making
- Developing respectful interprofessional (moral) teamwork

The term *parental autonomy* is often used in the context of neonatal care, without making a distinction between that term and *parental authority,* although most argue that autonomy can strictly be used only when making decisions for oneself, and that *parental authority* is the more correct term when referring to the role of parents in decision making for their newborn infants. The use of parental autonomy may be appropriate, however, when a parent has a vision of what it means to be a good parent, and it is necessary for that parent to choose to be allowed to parent in that *self-directed* way.

There are at least two primary reasons why neonatal health care professionals should show respect for parental authority/autonomy: (1) because of the rightful presumption that parents will make decisions that are in their child's best interests, and (2) as a means of equalizing the parental role in decisions with physicians who shape parental views, even at times without consciously intending to do so. Physicians need to be conscious of the impact of *their* authority and the power that derives from expertise or that follows from information given in a convincing manner. They also have to recognize that parents' ability to reason and to act in a self-directed way is often diminished in the presence of serious illness in their newborn infants.

In addition, there is a body of evidence and opinion that families may not want the decision-making authority that the prevailing bioethics emphasis on autonomy and self-determination advocates.[58,82] Numerous studies show that respect for mothers' or parents' autonomy does not require physician adherence to a strict informed consent interaction; a more nuanced application of this respect can be satisfactorily achieved by including parents in decision making within a trusting parent-physician relationship.[37,57] This inclusion may be more important than the parental "right" to make the final decision per se. Parents' insistence on their right and role as final decision maker may become their stance only after a breakdown in communication, or where respect for their role in a shared decision-making process has been disallowed or denigrated.

Too rigid or simplistic an interpretation and application of respect for parental autonomy by physicians is also problematic, such as when agreeing to a parental statement that "we want everything done." Without exploring what underlies this declaration, physicians may neglect the complexity of the situation and an unperceived parental fear of "abandonment."[26] Finding the right balance between respect for parental autonomy and the physician's role and responsibility in any decision-making process requires insight, empathy, and great analytical and communication skills.

Beneficence

Beneficence is the obligation of others to promote the best interests of patients who are unable to make autonomous health care choices. In newborns, this obligation is embodied in the concept of the "best interests of the newborn." This is a moral and legal *standard of judgment* that helps to establish the primacy of duties to infants, ensuring they be regarded as fully human individuals with interests, even when clearly unable to express their own value system. Pursuing a course of action in the best interests of an infant implies determining what treatment course has a more favorable benefit-to-harm ratio than other possible options—whether the treatment is likely to improve the newborn's condition or well-being, prevent it from deteriorating, or reduce the extent or rate at which it is likely to deteriorate, and whether the newborn's condition is likely to improve, remain the same, or deteriorate without the treatment. It also requires consideration of whether a less restrictive or less intrusive treatment course would be as beneficial as the treatment that is being proposed.

Determination of best interests requires an assessment of the child's potential *quality of life*. Quality-of-life considerations encompass the predicted cognitive and neurodevelopmental outcome, the potential for motor disability or other physical handicap (e.g., vision, hearing), and longer term concerns such as behavioral and learning difficulties or school problems. It also considers the requirements for repeated or prolonged hospitalization, surgery or medication, and the potential for pain and suffering to be endured. Quality-of-life considerations may also include less concrete medical states, such as the capacity for meaningful and potentially enjoyable interaction with other people and the environment.

The standard of best interests of the newborn acts as a threshold for judgment, yet the subjective nature of this assessment and the fact that the assessment is being done by surrogate decision makers must always be recognized. The procedural question of who are the rightful decision makers is of pivotal importance when parents, physicians, and nurses have different assessments of what is in the infant's best interests. Consider parents who believe in the preservation of life regardless of their infant's neurodevelopmental outcome; their perception of the benefits and harms of aggressive intervention may be quite different from the perception of a physician who places greater value on quality of life and relief of suffering. The best interests standard is not only a standard of judgment, but also a standard for possible intervention, if it is perceived by rightful decision makers that the infant's best interests are not being served by a particular course of action.

In most jurisdictions, the state confers the responsibility for health care decision making on the parents of young children because parents have a unique relationship with their children—one of concern, obligation, responsibility, and intimacy. Recognition of *parents' moral authority* in decision making presumes that parents would normally act to promote their children's best interests and endeavor to make health care decisions in that light.

The concept of best interests engenders much debate, not only because of the subjectivity of its assessment, but also because some authorities believe the concept is too complex: Defining "best" may be unattainable; it is culture specific, it is too individualistic, and it ignores the interests of others. The concept does imply, however, that the child's best interests should be pursued, even sometimes to the exclusion of family interests. Other authorities argue that it is legitimate for physicians and parents to consider family interests in making health care decisions for a sick newborn.[30] It has been shown that most neonatologists ascribe to an incorporation of family interests into decision making for their incompetent patients.[29]

Despite these definitional difficulties, "best interests of the newborn" is accepted as a guiding principle for decision makers to use because it unites under one standard different meanings and exhibits reasonableness, given the prevailing conditions.[41] Properly understood, the concept can serve as a powerful tool in settling disputes about how to make good decisions for individuals who cannot decide for themselves.

Nonmaleficence

The principle of *nonmaleficence* implies an obligation not to inflict *harm* on others. It has been closely associated with the maxim *primum non nocere* (first do no harm).[8] Although beneficence incorporates preventing and removing harm as part of promoting "the good" of a patient, the injunction not to *inflict* harm remains a distinct principle and requires intentionally refraining from actions that cause harm. Such harm is generally interpreted as *physical harm*, especially pain, disability, or death. Nonmaleficence requires that no initiation or continuation of treatment be considered without regard to the infant's pain, suffering, and discomfort; in situations in which a treatment is perceived as overly burdensome or harmful without foreseeable benefit, it should not be undertaken.

Justice

Justice is the dominant principle relating to *social cooperation*: It is expected to determine how social benefits, such as health care, are distributed via justified norms that are the product of human choices and values. Although justice is regarded as a guiding principle for any health care system, no single, simple, ideal implementation of it can suffice or satisfy all who wish to receive resources and be treated in ways that safeguard their rights. Generally, concepts of justice range from the broader utilitarian calculus to promote the greatest good for the greatest number in underwriting the *distribution of resources* (i.e., *macroallocation*) to a more narrowly focused equality of opportunity for each individual (*microallocation*). Justice in the distribution of resources would require (1) that patients in similar situations have access to the same health care, and (2) that the level of health care available for one set of patients takes into account the effect of such a use of resources on other patients.

Reasoning in the context of allocation of resources for the individual patient allows that fairness is an important consideration, but is not the fundamental standard in this interaction. Microallocation issues are seldom appropriate at the bedside, although some consistency between macrodistribution and microdistribution must exist if the two systems are to operate smoothly, because the two are inevitably linked.

In every system, the provision of neonatal services requires guidelines to be developed for determining appropriate use of these costly and often limited resources. Priorities must be set and justified by authorities in decision-making positions. Any changes in the way neonatal care is delivered also need to be fair and accessible, and open and challengeable. Disputes should be worked out based on the acceptance of objective measures and trust in the integrity and fairness of the process and the individuals responsible for management of the process. The fact that the principle of justice has not been at the forefront of bioethical discourse at the neonatal bedside may change with increasing recognition of this deficiency, particularly in times of financial constraint; how resources for sick newborns are used and justified may become more critically and ethically questioned.

KEY TERMS AND CONCEPTS

Communication with Parents

Parents require complete and truthful information about their infant—the diagnosis and prognosis, the available treatment options (including, where relevant, the option of no treatment), the benefits and harms associated with each option, and the limits of available technology. The manner in which this information is communicated influences parents' understanding of the situation, their ability to discuss moral issues and values openly, and their ability to participate effectively in a decision-making process (Box 3-2). Information communicated in an honest and respectful manner is likely to foster trust; information that is confusing, incomplete, evasive, or conveyed in a hurried or dismissive way is unlikely to do so. *Transparency* in communication is crucial: It emphasizes the physician's reasoning, builds an understanding of the illness, makes the connection between data and their implications, and tempers unrealistic parental expectations.[38]

As medicine advances, physicians and parents must sometimes struggle with information that is at the limits of medical knowledge and where the implications of findings are uncertain. The manner in which *medical uncertainty,* specifically *prognostic uncertainty,* is (or is not) communicated is extremely important and influences subsequent decision making. Neonatal physicians have been described as dealing with prognostic uncertainty via one or more of three strategies: (1) a statistical approach, (2) a wait-until-certainty approach, or (3) an individualized prognostic approach.[65]

With a *statistical approach,* decisions are made on the basis of an analysis of the known outcomes of infants with that condition—be it extremely low gestational age or a major chromosomal or congenital anomaly. The primary objective is to avoid enhancing the survival of infants with conditions where the known outcome data show profoundly poor prognoses, even if this means that some potentially viable infants do not survive.

The *wait-until-certainty approach* begins with treatment for almost every infant with any chance of survival. It establishes a momentum in favor of continuing treatment until a major medical event does or does not occur. The possibility of withdrawal or discontinuation of life-sustaining medical treatment is considered only when severe, adverse medical findings become unequivocally evident. A problem with this strategy is that frequently, even with the passage of time, uncertainty persists. The issue is not certainty per se, but rather the degree of certainty required by physicians and parents to facilitate decision making. This approach denies the ethical complexity of situations by failing to address the moral and the medical uncertainty and risks relegating parents and other members of the health care team to the role of bystanders as the medical course unfolds.

BOX 3–2 Guidelines for Respectful Communication with Parents

Create an environment for communication that encourages parents' participation and their becoming as fully informed as possible
Identify and remove barriers that limit parents' role in communication (e.g., language, physical distance)
Communicate with parents: at the time of admission, at any crisis point in their child's NICU course, via periodic reviews of longer stay patients, and other unstructured opportunities
Encourage parents to seek clarification of information at any point by requesting an appointment with the child's responsible physician
Provide open, truthful communication at all times
Provide information as accurately as possible and with as much certainty of diagnosis and prognosis as is possible in each clinical situation
Identify areas of medical uncertainty
Use easily understandable language
Assess family communication preferences, and attempt to communicate within those parameters
Be preemptive in communication (i.e., foresee what problems or issues may arise in the child's course)
Be proactive in communication in any clinical situation in which a poor outcome is predicted
Convene meetings with both parents when important decisions need to be made
Keep parents informed of any special investigations/tests that are planned in the course of management of their child
Recognize the need for time for processing and absorption of information
Ensure consistency and continuity of communication in the face of medical staff changes and handovers
Practice open, honest, and timely disclosure regarding medical error

NICU, neonatal intensive care unit.

With an *individualized prognostic strategy,* treatment is initiated for all infants who have a reasonable chance of survival. Decision making solely on the basis of biomedical factors is avoided, and the ongoing moral responsibility of the decision makers is emphasized in an effort to involve parents and the health care team in navigating the ensuing prognostic uncertainty. This approach avoids the extremes of either withholding treatment from all infants who fall below a minimum threshold or treating all infants until the outcome is absolutely certain.

The *timing* of any communication with parents is crucial. Ideally, parents' readiness to receive information and their coping resources should be ascertained, so that appropriate information is shared with consideration of their adaptation to the medical setting. In acute situations, if an urgent decision is required, the physician needs to move the relationship rapidly, however, from one of "moral strangers" to one in which moral issues can be openly discussed.

Obtaining *parental consent* for each planned intervention for the infant is often the prompt for communicating with parents in the NICU. Some authorities may regard that obtaining formal, informed consent from parents for virtually every neonatal test or procedure is a means of maintaining a high standard of ethical care. Ensuring that parents are kept up to date and advised of treatment plans is important; however, information gathered from an ethnographic study showed that parents did *not* want to be asked to consent to every procedure.[1] They often felt overwhelmed when asked to consent for routine and minor procedures and felt they were given the illusion that they could or should say stop when there was no real choice and no time to learn more about each procedure. It was also clear that the more the staff offered information and time to listen to parents when *not* driven by a consent process, the easier it was for parents to discuss questions and dilemmas on fairly equal terms. When consent was required, parents emphasized the need for a two-way informed agreement between fairly equal partners with established mutual trust and respect.

A sound *patient-physician relationship* is a *sine qua non* of good medicine, for it is within this relationship that physicians exercise their humanity, understanding, and respect for the values of others. Every communication interaction with parents is an opportunity for relationship building. The ideal model in *adult* patient-physician relationships is considered to be the *deliberative-interactive model,* wherein physicians not only help the patient with clarification of his or her values, but also strive to make their own reasoning transparent for the patient to appreciate the many factors that inform their professional recommendation.[21] In neonatal medicine, the physician's communication relationship is with the parents (or legal guardians) of the newborn, and the optimal parent-physician relationship aims to mirror the deliberative-interactive model, wherein physicians provide parents with accurate and timely information (with as much medical certainty as possible), and encourage and empower them to identify their values and treatment preferences. This model of relationship respects parental authority, encourages the physician's expression of his or her own clinical judgment, and, in so doing, promotes the best interests of the newborn and the family.

Environmental and contextual factors challenge the achievement of this parent-physician relationship, including the fast NICU pace and the demands of time and scheduling changes. There may also be personal *physician-related factors* that need to be overcome, such as physicians' reluctance to express their views, a focus on short-term goals, an inherent avoidance of prognostication and discussion about outcomes, and a fear of damaging the relationship by being the bearer of bad news. Nevertheless, it is incumbent on physicians to attempt to develop a *therapeutic alliance* with parents and to engage in relationship building with them. The responsibility for a parent-physician relationship always rests with the physician.

Teams and Communication

Although it is important that the responsible physician attempt to integrate all of the important information and maintain a consistent relationship and pattern of communication with parents, neonatal intensive care is provided by many clinicians with expertise in different fields. This situation requires an understanding among the team members of the differences in responsibility in communication with parents, such as when conveying day-to-day quantifiable, objective information, or when communicating severe diagnoses or the more speculative, prognostic significance of specific findings. Although the responsibilities of each discipline are generally known, in certain situations communication boundaries may need to be defined to minimize fragmented and inconsistent information. Interdisciplinary meetings, in which the contribution of all the practitioners involved with the family are combined, are crucial in ensuring that consistent patterns of communication are maintained.

FAMILY-CENTERED NEONATAL INTENSIVE CARE

Family-centered care is a philosophy that acknowledges the sick newborn infant's place within the social unit of the family, and that cultural, emotional, and social support by the family is an integral component of the infant's care. This concept also considers the effects of a decision on all family members, their responsibilities toward one another, and the burdens and benefits for each member of the family. Family-centered care shapes policies, programs, facility design, and day-to-day interactions, but should reflect values and attitudes more than protocols. The potential benefits of a family-oriented approach include improved parental satisfaction with care and decision making, decreased parental stress, greater parental ability to cope with their infant's appearance and behavior, improved success with breast feeding, and increased parental comfort and competence for postdischarge care.[19]

Recognition of the child's place within the family highlights the cultural, religious, and spiritual dimensions of families' lives and may bring to light significant diversity within these domains. In a pluralistic society, parents and physicians are unlikely to share the same values, cultural systems, personal histories, and experiences, and at times of stress these differences may present health care providers with significant challenges.

The first challenge is to recognize, understand, and respect the cultural, religious, and spiritual views and values of parents and families. Meeting this first challenge is crucial because misperceptions caused by a lack of sensitivity can lead to inappropriate care or poor clinical outcomes. *Cultural competence* is more than sensitivity to cultural norms different from one's own. Cultural competence implies an ability to interact effectively with people of different cultures and comprises four components: (1) the individual's awareness of his or her own cultural worldview, (2) the individual's attitude toward cultural differences, (3) the individual's knowledge of different cultural practices and worldviews, and (4) the individual's cross-cultural skills.[50] Developing cultural competence results in an ability to understand, communicate with, and interact effectively with people across cultures.

The second challenge for neonatal health care providers involves the limits of tolerance—where to draw the line between accepting patterns of decision making between couples or within families that contrast markedly with the prevailing cultural norm of shared parental responsibility for decision making. A third challenge arises because not only are parents and physicians products of their own respective cultures, but also their interactions occur within a further "culture"—that of medicine and intensive care itself—with its own values, assumptions, and understanding of what should be done.

Although the health care team should recognize how families' interests are shaped by social, cultural, and other contexts, it is important *not to stereotype* the members of specific social, cultural, ethnic, or religious groups. Individuals' affiliations may not be predictive of their beliefs and values in the care of their infant, and the health care team should regard each patient and family as *unique* and attend carefully to their specific views and values.

When attentiveness to the views and values of families is difficult because of language barriers, professional interpreters should be used. Use of an interpreter is advisable for three reasons: (1) it ensures that parents' views are available to the health care team, (2) it removes the burden on family members or friends for the transfer of information, and (3) it limits the potential for miscommunication. In certain situations, a *cultural interpreter* not only can facilitate language comprehension, but can also provide useful information about cultural norms and traditions that are unfamiliar to the health care team. Access to high-quality interpretation services is an essential component of ethically and culturally sensitive care.

Religion and the more general concept of *spirituality* as a major determinant of culture, tradition, and family values often needs to be addressed with parents, particularly when end-of-life decision making is undertaken. A qualitative questionnaire study completed by parents after their child's death revealed the emergence of four explicitly spiritual/religious themes: prayer, faith, access to and care from clergy, and belief in the transcendent quality of the parent-child relationship that endures beyond death.[66] Other significant themes with a religious/spiritual dynamic included finding meaning, hope, trust, and love. Similar findings were obtained in a study focused on the delivery room consultation: mothers stated that religion, spirituality, and hope were the major factors that guided their decision making.[9] The implication of these studies is that health care teams need to consider whether they have or need to create an environment that is hospitable to, and supportive of, religious or spiritual practice, that clinical staff recognize parents' spiritual needs and provide access to hospital chaplains and community clergy, and, on a deeper level, appreciate parents' religious and spiritual perspectives in prenatal consultations and end-of-life discussions.

Consensual Decision Making

Consensual decision making implies that the parents and the physician/health care team are involved in the decision-making process—that they share relevant information with each other, they express their treatment preferences, and when a final decision is made, all parties are in agreement. The ideal consensual decision is one in which neither party feels individually responsible for that decision. Parents often feel *burdened* by what they perceive as their responsibility for the decision. When the process of consensual decision making is handled well by the physician/health care team, the burden of the consequences of the decision is shared.

Team Consensus in Ethical Issues

How teams that normally function synergistically in terms of purely medical matters operate when dealing with ethical issues may be very challenging, not only because of the difficulty in defining roles and responsibilities in matters of ethical deliberation, but also from a more fundamental aspect in that the two major professions, medicine and nursing, have differed over time in their preparation for this practice.[71] Medical professionals tend to view their role as one in which the best science is in the patient's best interest, with less attention to deeper questions such as the goals and limits of medicine and the moral core of the profession. Seeing things from the patient's point of view, relating to the patient's family in a nonjudgmental way, emphasizing the healing potential of communication, and having respect for patients' informed choices seem to be more intrinsic to the nursing tradition. In interactions concerning the end of life of a neonate, physicians see the focus of their moral obligations on decision making with parents, whereas neonatal nurses see their moral obligations focused on the process and moment immediately surrounding death.[22] What is needed, according to Storch and Kenny,[71] is "shared moral work": Interprofessional practice implies that individual health care practitioners are aware of their own professional values and the need to work collaboratively, build understanding, and work toward resolution with other professionals, particularly when different perspectives threaten team function. The beneficial effects of multidisciplinary participation and perspectives have been well shown in teams developing guidelines for decision making, such as those at the limits of viability.[6,36]

CLINICAL APPLICATIONS IN SPECIFIC MORAL PROBLEMS

Refusal of Treatment during Pregnancy

When a pregnant woman acts in such a way as potentially to create a serious risk of harm for her developing fetus, some authorities argue that state intervention is morally justified in an effort to promote fetal health and well-being. Other authorities maintain that such intervention not only violates the pregnant woman's autonomy, integrity, and privacy, but also undermines the principle of reproductive freedom.[24]

Authorities who advocate state intervention consider the principle of reproductive freedom to be morally unsound: Whatever rights a pregnant woman may have to direct the course of her pregnancy, they do not include the right to harm the fetus. This perspective ignores the contested moral status of the fetus; the fetus-to-be-born, in contrast to the infant or the pregnant woman, is not uniformly recognized as a person with full moral standing. This perspective also suggests that the pregnant woman intentionally seeks to harm her fetus, which is generally false.

Other participants in this debate readily acknowledge that the fetus does not have the same rights as a person, and that the pregnant woman may not intend to harm her fetus. They

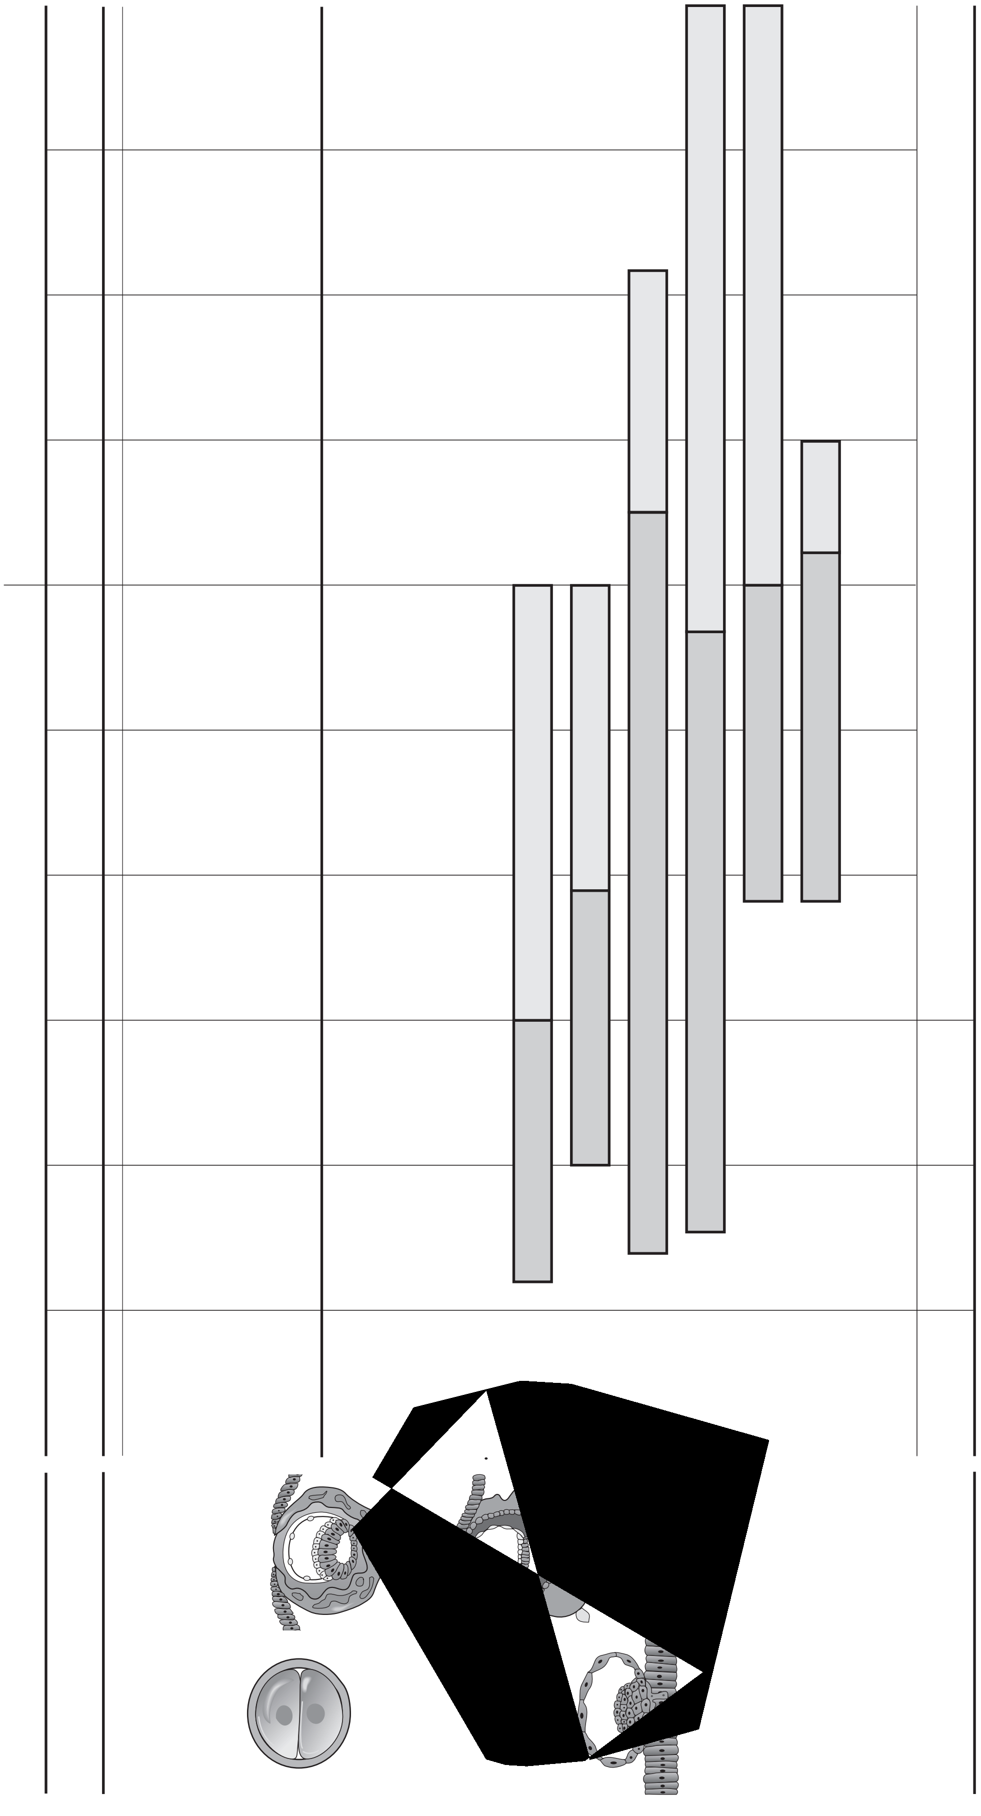

TABLE 8–3 FDA Guidelines Categorizing Pregnancy-Related Risk

Category	Interpretation
A	Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to show risk to the fetus
B	No evidence of risk in humans. Either animal findings show risk (but human findings do not), or, if no adequate human studies have been done, animal findings are negative
C	Risk cannot be ruled out. Human studies are lacking, and animal studies are either positive for fetal risk or lacking as well. Potential benefits may justify potential risk
D	Positive evidence of risk. Investigational or postmarketing data show risk to fetus. Potential benefits may outweigh risk
X	Contraindicated in pregnancy. Studies in animals or humans, or investigational or postmarketing reports have shown fetal risk that clearly outweighs any possible benefit to the patient

FDA, U.S. Food and Drug Administration.

during the first trimester, if an alternative therapy is inappropriate, the lowest possible lithium dose should be used. Finally, certain drugs are known teratogens, but the underlying disorder may contribute to birth defects independently. Women with epilepsy are at increased risk of fetal malformations such as orofacial clefts, independent of whether or not they are taking anticonvulsant therapy.

Diagnostic Imaging

Radiographic imaging modalities are widely used in inpatient and outpatient settings. Safety of ionizing radiation exposure in pregnancy is an important concern because of the association of ionizing radiation with prenatal death, malformation, and carcinogenesis. It is necessary to weigh the risk of exposure versus the risk to the mother and fetus of a delayed diagnosis. With proper test selection, shielding, and procedure modifications, fetal risk can be significantly reduced or eliminated.

Common radiologic studies, such as computed tomography scan of the chest or dental x-rays, typically expose the fetus to much less than 5 rad of radiation (Table 8-4). At these levels, there has been no evidence of increased risk of mental retardation, fetal anomalies, or pregnancy loss. The risk of childhood leukemia with an exposure of 1 to 2 rad increases to 1 in 2000, a 1.5-fold increase above the baseline risk of 1 in 3000.[1]

Exposure greater than 10 rad has been associated with an increased risk of malformations. Diagnostic imaging rarely, if ever, exposes the fetus to this level of radiation, however. Iodinated contrast materials can cross the placenta and produce transient effects in the developing fetal thyroid. Although not contraindicated, iodinated contrast material should be used with great care.

Magnetic resonance imaging (MRI), which uses electromagnetic radio waves to generate images, has not been associated with any harmful effects to the developing fetus. Gadolinium, the contrast agent most commonly used in MRI, crosses the placenta. There has been limited evaluation of its safety, and it is not recommended for use in pregnancy.

Ultrasonography is an important tool in obstetrics. Although there has been some concern regarding elevation of tissue temperature with prolonged use, there is no reliable evidence of harm to the human fetus as the result of standard, medically indicated ultrasonography. When used appropriately, ultrasonography can provide important information regarding gestational age and fetal anatomy. The casual use of ultrasonography for fetal pictures or sex determination is not justified.[6]

TABLE 8–4 Estimated Average Fetal Exposure from Select Imaging Studies

Procedure	Fetal Dose (mrad) for an Average Study
Chest x-ray (PA and lateral)	<1
Abdominal plain film	200-300
Intravenous pyelogram	400-900
Barium enema	700-1600
Cervical spine x-ray	<1
Dorsal spine x-ray	<1
Lumbar spine x-ray	400-600
Lumbosacral area	200-600
Upper GI series	50-400
Dental x-rays	0.01
Mammography	Negligible
CT scan of chest	30
CT scan of abdomen	250
Perfusion lung scan with Tc 99m	6-12
Ventilation lung scan	1-19
Pulmonary angiography via femoral route	221-374
Pulmonary angiography via brachial route	<50

CT, computed tomography; GI, gastrointestinal; PA, posteroanterior.

Airline Flights

The amount of cosmic radiation received during commercial flights is much less than the levels associated with fetal risk. A transcontinental flight across the United States would result in an exposure of approximately 6 mrad.[9] Pregnant women should keep well hydrated and move their lower extremities when possible to avoid venous stasis and thromboembolic events.

CONGENITAL ANOMALIES AND ULTRASONOGRAPHY

Ultrasonography has become an important tool in obstetrics and gynecology over the past two decades. Geneticists use ultrasonography as a way to characterize dysmorphology in utero.

Congenital abnormalities occur in 3% to 4% of live births and have several causes—single-gene defects, chromosomal abnormalities, teratogens, multifactorial, or unknown reasons. Congenital anomalies can be divided into three categories depending on the mechanism underlying the defect: malformations, deformations, and disruptions. Malformations involve intrinsic abnormalities in the genetic programs controlling development. The syndactyly that is associated with Apert syndrome is the result of a mutation in a gene encoding for fibroblast growth factor receptors. Conversely, deformations are caused by extrinsic factors physically impinging on otherwise normal tissue. An example of this is arthrogryposis, or contractures of the extremities. This condition can be caused by a prolonged leakage of amniotic fluid, resulting in fetal crowding. Disruptions, the final category, are the consequence of fetal tissue destruction. They can be the result of vascular insufficiency or mechanical damage. Amniotic band syndrome results in the partial amputation of a limb.

Assessment of an infant with birth defects requires a careful review of prenatal exposures and maternal illnesses. When evaluating birth defects, it is important also to consider whether a defect occurred in isolation or is part of a pattern, which may suggest a syndrome. Imaging studies or laboratory examinations may also help elucidate the underlying pathophysiology of an anomaly.

ACOG states that “ultrasound examination is safe for the fetus and can be used for the diagnosis of many major and minor fetal anomalies.”[6] Ultrasound examinations fall into three categories: limited, standard, or specialized. A limited examination is one that is performed to address a specific question, such as placental location, or to confirm fetal cardiac activity. It cannot replace a standard ultrasound examination, which is ideally performed between 18 and 20 weeks’ gestation. A specialized ultrasound examination, such as fetal echocardiography, fetal Doppler studies, or additional biometry, is performed when an anomaly is suspected based on family history, laboratory aberrations, or discovery during standard ultrasound examination. An abnormality seen on ultrasound examination is a common reason that patients opt to undergo invasive prenatal diagnosis.

An example of the utility of ultrasonography is the case of fetal pyelectasis, or hydronephrosis. Defined as a renal pelvic diameter of greater than or equal to 4 mm, this finding is present in 3% of euploid fetuses and is a relatively common finding. Postnatal evaluation shows that although most cases resolve, conditions such as ureteropelvic junction obstruction and vesicoureteral reflux may be identified in some infants.[40] The fact that the potential issue can be identified prenatally and results in postnatal follow-up obviates the possibility of a child with chronic renal impairment owing to silent infection and inflammation.

In a review of 36 published studies, the overall sensitivity for detecting fetal anomalies was 40.4% (range 13.3% to 82.4%), indicating that these detection rates greatly depend on the incidence of anomalies in the population studied and sonographer experience. It has been observed that 50% of fetuses with Down syndrome have no findings on prenatal ultrasound examination. When an examination is performed, the patient should be counseled regarding the benefits and limitations of ultrasonography.[6]

First-trimester ultrasonography has been traditionally used to confirm an intrauterine pregnancy, to estimate gestational age, and to evaluate pelvic anatomy. Since the introduction of first-trimester aneuploidy screening (see separate section), there has been interest in screening for structural anomalies in the first trimester. There is now extensive literature on the use of first-trimester testing in the detection of fetal anomalies, and in expert hands, a very thorough examination is possible. Prospective studies have shown a 44% to 50% detection rate of major anomalies in the first trimester.[15] Further refinement in this technique as a screening tool is required before it can be considered part of routine practice.

Three-dimensional ultrasonography has some unique advantages over two-dimensional ultrasonography. Its ability to acquire and manipulate an unlimited number of planes allows for the quantification of organ volume and the ascertainment of images inaccessible by two-dimensional technology. Despite these technical advantages, however, consistent utility has not been determined. Potential areas of clinical benefit include evaluation of NTDs and facial anomalies.

SCREENING MODALITIES

Screening for Aneuploidies

Current guidelines from ACMG and ACOG recommend that all pregnant women, regardless of age, have the option to undergo invasive diagnostic testing for fetal aneuploidy. After reviewing the benefits and limitations of screening and diagnostic modalities with their health care provider, patients have the option to undergo screening tests for fetal aneuploidy and NTDs (Table 8-5).

FIRST-TRIMESTER SCREENING

First-trimester screening, which involves an ultrasound examination and ascertainment of serum markers, is performed between 10 4/7 and 13 4/7 weeks’ gestation. The ultrasound examination involves measurement of the nuchal translucency, a fluid-filled space behind the fetal neck. An increased nuchal translucency is significantly associated with aneuploidy, including Down syndrome. ACOG recommends that patients with a fetal nuchal translucency of 3.5 mm or greater be offered targeted ultrasonography

TABLE 8–5 Elevation and Depression of Parameters Used in First-Trimester and Second-Trimester Screening Tests

	FIRST-TRIMESTER SCREEN			SECOND-TRIMESTER SCREEN			
	Nuchal Translucency	*PAPP-A*	*Free β-hCG*	*uE_3*	*AFP*	*Free β-hCG*	*Inhibin A*
Trisomy 21	Increased	Decreased	Increased	Decreased	Decreased	Increased	Increased
Trisomy 18	Increased	Decreased	Decreased	Decreased	Decreased	Decreased	Unchanged
Trisomy 13	Increased	Decreased	Decreased	Decreased	Decreased	Decreased	Unchanged
Neural tube defect	NA	NA	NA	Unchanged	Increased	Unchanged	Unchanged

AFP, α-fetoprotein; β-hCG, human chorionic gonadotropin β subunit; NA, not applicable; PAPP-A, pregnancy-associated plasma protein A; uE_3, unconjugated estriol.
From Nussbaum RL et al: *Thompson and Thompson genetics in medicine,* 7th ed, Philadelphia, 2007, Saunders, p 449.

with or without echocardiogram. Detection of Down syndrome with nuchal translucency alone is 70%. When combined with two serum markers, pregnancy-associated plasma protein A (PAPP-A) and human chorionic gonadotropin (hCG), the detection rate increased to 79% to 90%. Results are reported as an adjusted risk for Down syndrome. Patients should be informed of this number to make decisions.[12]

SECOND-TRIMESTER SCREENING

The second-trimester maternal serum screen for aneuploidy, particularly trisomies 18 and 21, and NTDs is performed between 15 and 20 6/7 weeks of pregnancy. Maternal serum α-fetoprotein (AFP), hCG, and unconjugated estriol, known as the "triple screen," has an aneuploidy detection rate of 65%. With the addition of a fourth marker, inhibin-A, to create the "quad screen," the detection rate increases to approximately 80%. The detection of NTDs is discussed subsequently. Results are reported as age-adjusted risks and, similar to first-trimester screening, should be reported to patients to make decisions regarding their desire for invasive testing.

Strategies to increase the detection rate to greater than 90% include the integrated screen, in which nuchal translucency measurement and PAPP-A results from the first trimester are combined with the quad screen in the second trimester. The downside for this strategy is that the result is not available until the second trimester. Sequential screening involves disclosure of the patient's first-trimester screening results. If the patient opts not to undergo invasive testing, the quad screen is performed in the second trimester, and the second-trimester risk is calculated with consideration of the first-trimester screening results.[13]

Screening for Multifactorial Disorders

SERUM α-FETOPROTEIN

Maternal serum AFP is an important tool in screening for NTDs. AFP is a fetal-specific molecule that is synthesized by the fetal yolk sac, gastrointestinal tract, and liver. The maternal serum AFP concentration is usually significantly lower than fetal plasma or amniotic fluid.

Drawn between 15 and 20 weeks' gestation, maternal serum AFP screening should be offered to all pregnant women. Although it is intended as a screening test for open NTDs, other abnormalities, such as ventral wall defects, may also cause an increase in maternal serum AFP. Results from the examination are reported as multiples of mean (MoM) based on gestational age. A value greater than 2.5 MoM is considered abnormal. Clinicians may opt to repeat the test after one moderately elevated result because one third are below the threshold on repeat analysis. If this occurs, a return to below threshold has not been associated with an increase in false-negative results.[14]

If the value remains persistently elevated, or the clinician opts not to repeat the test, the next step is to perform a detailed ultrasound examination and discuss the option of amniocentesis with the patient. Amniotic fluid AFP and amniotic fluid acetylcholinesterase (AChE) are the two main analytes evaluated for detection of NTDs. An elevation of AFP and AChE values suggests an open fetal NTD with 96% accuracy with a false-positive rate of 0.14%. Contamination of the amniotic fluid sample with blood accounts for half of false-positive results.[37] Fetal karyotype should also be performed using the amniotic fluid obtained. An elevated maternal serum AFP in the second trimester that cannot be explained by fetal structural abnormality or underlying maternal conditions is associated with poor fetal outcome, including increased risk of intrauterine fetal demise, placental abruption, and preeclampsia.[25]

Screening for Mendelian Disorders

Preconceptual and prenatal parental carrier screening is an effective way to prevent or prepare for neonatal diseases. Discussions of testing strategies for common mendelian disorders follow.

SCREENING FOR HEMOGLOBINOPATHIES

As part of routine obstetric care, all women in the United States have a complete blood count early in pregnancy. This simple test helps identify women at risk for hemoglobinopathies and thalassemias. According to ACOG guidelines, women of African descent should have a hemoglobin electrophoresis along with a complete blood count. Additional factors to help distinguish couples at risk for a child affected by a hemoglobinopathy or thalassemia include microcytic anemia with normal iron status; family history of a hemoglobinopathy or thalassemia; or a high-risk ethnic background, such as Mediterranean or Southeast Asian descent. Women who have any of these risk factors should also undergo hemoglobin electrophoresis. If a hemoglobin variant or thalassemia is discovered, the woman's partner should be evaluated. When the father is determined also to be a carrier or is unavailable for testing, the patient should be offered genetic risk assessment and prenatal testing.[5]

CARRIER SCREENING FOR CYSTIC FIBROSIS

Cystic fibrosis, the most common autosomal recessive disease in live-born infants, is a multisystem disorder that is the result of mutations of a large gene on chromosome 7 that encodes the cystic fibrosis transmembrane conductance regulator (CFTR) protein. The condition is characterized by chronic pulmonary disease, pancreatic insufficiency, and liver disease. Although there have been more than 1200 mutations identified in the *CFTR* gene, certain mutations, such as ΔF508, have a much greater incidence in the population. In whites, the carrier rate is 1 in 25, and ΔF508 accounts for 75% of cystic fibrosis cases. The carrier rate differs based on ethnic origin; individuals of Asian descent have the lowest carrier rate, approximately 1 in 90 (Table 8-6).[2] ACOG recommends that carrier screening be offered to all couples regardless of ethnicity. It is important for providers to discuss with their patients that a negative screen decreases the risk of being a carrier, but does not eliminate it completely because screening does not test for all possible mutations.

JEWISH CARRIER SCREENING

The *founder effect* refers to the overrepresentation of specific alleles in an inbred population. This mechanism has been documented in the Jewish community, particularly individuals of Ashkenazi heritage (eastern European). Tay-Sachs disease is the most well known of these disorders. Because of communal efforts and professional guidelines, the incidence of this disease has declined remarkably, however, to the point that most children born with this disorder are not of Jewish heritage. Carrier screening, prenatal diagnosis, and culturally sensitive marital planning in regard to this autosomal recessive disease all were applied in this effort dating back to the 1970s. Since that time, the underlying genetic mutations are now known for several more similar diseases known collectively as the *Jewish genetic disorders*. As a group, the carrier frequency is very significant—one in five Ashkenazi Jews carries a mutation for one of these autosomal recessive disorders.

Culturally sensitive preconceptual and prenatal carrier screening is an important tool in preventing or preparing for these devastating diseases. The current recommendation from ACMG is to offer carrier screening to individuals who identify their background as Ashkenazi Jewish for the following diseases: cystic fibrosis, Canavan disease, familial dysautonomia, Tay-Sachs disease, Fanconi anemia (group C), Niemann-Pick (type A) disease, Bloom syndrome, mucolipidosis IV, and Gaucher disease (Table 8-7). Other disorders, such as glycogen storage disease type Ia and maple syrup urine disease, are likely to join this panel in the future. In couples with one partner of Ashkenazi Jewish background, that partner should be screened first, and if he or she is found to have a positive result, the other partner (regardless of background) should be screened for that disorder.[16]

CARRIER SCREENING FOR SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy (SMA) is a progressive neuromuscular disease resulting from degeneration of spinal α motor neurons. Childhood SMA is divided into three clinical groups, types I, II, and III SMA, depending on age of onset and clinical sequelae. With a live birth rate of 1 in 10,000, SMA is the second most common fatal autosomal recessive disorder after cystic fibrosis. The SMA-determining gene, *SMA1,* is located on 5q13. The carrier rate of an abnormal allele is 1 in 40 to 1 in 60, and is consistent throughout all ethnic groups. In 95% of cases, this abnormality is a deletion in exon 7 of *SMA1*. ACMG has recommended that voluntary SMA carrier testing be offered to all couples regardless of race or ethnicity. The sensitivity of the carrier screening test is approximately 94%. A negative screening test for both partners reduces the possibility of an affected offspring significantly, but does not eliminate it entirely.[30]

DIAGNOSTIC MODALITIES

After genetic counseling, some couples may opt to undergo diagnostic testing as opposed to prenatal screening. Others choose diagnostic testing after an abnormal screening result or ultrasound finding.

TABLE 8–6 Carrier Rates Based on Ethnicity and Likelihood of Being a Carrier for Cystic Fibrosis after a Negative Screening Result

Racial or Ethnic Group	Carrier Rate Before Testing	Carrier Risk after Negative Test Result
Ashkenazi Jewish	1/24	~1/400
Non-Hispanic white	1/25	~1/208
Hispanic American	1/46	~1/164
African American	1/65	~1/186
Asian American	1/94	~1/184

TABLE 8–7 Jewish Genetic Disorders: Carrier Frequency and Disease Characteristics

Disease Name	Carrier Frequency	Disease Characteristics
Gaucher disease type 1	1:18	Lysosomal storage disease caused by deficiency of the enzyme glucocerebrosidase. Enlarged spleen, liver malfunction, bone marrow dysfunction result from an accumulation of its substrate, glucocerebroside. Depending on disease severity, affected individuals can survive into adulthood
Tay-Sachs disease	1:31	Deficiency of enzyme hexosaminidase A, which results in accumulation of fatty acids known as gangliosides in the brain. Children with Tay-Sachs appear normal and then develop progressive mental and physical deterioration, including blindness, deafness, and dysphagia. Different variants are characterized by age of onset
Familial dysautonomia	1:31	Result of mutations in the *IKBKAP* gene, which encodes for the IKAP protein (IkB kinase complex associated protein). Presence of the abnormal protein affects the development of neurons in the sensory and autonomic nervous system resulting in pain insensitivity, poor growth, and labile blood pressure
Canavan disease	1:41	Defective *ASPA* gene results in accumulation of *N*-acetyl aspartate, which interferes with the neuronal myelin sheath. Symptoms include mental retardation, loss of motor function, and megalocephaly
Fanconi anemia group C	1:89	Mutations in 13 different genes involved in DNA repair complex are known to cause Fanconi anemia, characterized by skeletal anomalies, short stature, and increased risk of malignancy and aplastic anemia
Niemann-Pick disease type A	1:90	Lysosomal storage disease caused by a mutation in the *SMPD1* gene, which results in accumulation of sphingolipids in neuronal, hepatic, and splenic tissue
Bloom syndrome	1:107	Mutations in the *BLM* gene, a member of the DNA helicase family, result in increased susceptibility to early cancers and phenotypic features that include high-pitched voice, distinct facies, telangiectasias, skin pigment changes, and hypogonadism
Mucolipidosis IV	1:127	Disruption of a nonselective cation channel, *TRPML1,* results in abnormal lysosomal storage and neurodegeneration

Chorionic Villus Sampling

Chorionic villus sampling (CVS) involves procuring a small sample of the placenta for genetic diagnosis. Although not fetal tissue, the placenta is embryologically derived from the same trophoblastic cells as the fetus, and most often has the same karyotype as the fetus. Usually performed between 10 and 13 weeks' gestation, CVS is an ambulatory procedure. Using ultrasound guidance, the placental villi can be obtained through a transcervical or transabdominal approach depending on placental location. CVS enables diagnosis of genetic disorders in the first trimester, giving patients more time to make decisions about the pregnancy, including the opportunity for first-trimester termination if they choose.

When the villi have been obtained, the medium is placed onto a plastic tissue culture dish to evaluate the sample. If the sample appears inadequate, the operator may opt to take a second pass to obtain more villi. Blood clots and maternal decidua can be separated from the villi, and these cleaned villi can be transferred to different media for further evaluation, including fluorescence in situ hybridization (FISH) studies and long-term culture. AFP testing cannot be performed on CVS tissue samples. It is impossible to assess risk of NTDs through CVS.

The most serious complications associated with CVS are damage to the fetus and pregnancy loss. CVS has been associated with an increased risk of transverse limb and oromandibular defects. It is hypothesized that these defects are caused by disruption of the vascular system. The overall risk for transverse limb defects after CVS is approximately 1 in 3000, with most defects occurring if CVS is performed before 9 weeks' gestation.[11] Women contemplating CVS can be reassured that if performed after 9 weeks' gestation, the risk of limb defects associated with CVS is low and approaches the baseline population risk.[4]

The pregnancy loss rate after CVS is complicated by the fact that the background risk of pregnancy loss in the first trimester is greater than in the second trimester. Operator experience, number of insertions, and gauge of catheter used all play a part in determining the procedure-related risk of CVS. More recent data suggest that the pregnancy loss rate attributable to CVS approaches the rate of midtrimester amniocentesis, approximately 1 in 500 pregnancies.[27]

Two other important considerations with CVS are sampling success and the concept of confined placental mosaicism. On first attempt, transabdominal CVS results in an adequate sample 98% of the time versus 96% for transcervical CVS.[33] Culture of mesenchymal cells of CVS samples reveals the existence of trisomies not present in the conceptus in approximately 1% of cases. In this scenario, an amniocentesis is warranted to confirm the fetal karyotype. Patients should be informed of the small risk of an inadequate sample or the need for additional testing secondary to placental mosaicism during their genetic counseling session, before opting for diagnostic testing.

Amniocentesis

Amniocentesis, a procedure to withdraw amniotic fluid from the uterine cavity, is most commonly performed either for prenatal genetic studies or for evaluation of fetal lung maturity (performed in the third trimester). It can also be used as a diagnostic tool for evaluation of intra-amniotic infection or as a therapeutic procedure to remove excess amniotic fluid. The rest of this section focuses on amniocentesis for the purposes of genetic diagnosis.

Although technically possible after 11 weeks' gestation, an amniocentesis is usually performed between 15 and 22 weeks' gestation. Before 14 weeks' gestation, the complication rate, particularly orthopedic malformations, is higher because of incomplete fusion of the amnion, chorion, and decidua parietalis. After 22 weeks, two potentially serious scenarios exist: (1) the procedure provokes labor or rupture of membranes resulting in a periviable delivery, or (2) abnormal results arrive after the fetus has entered into the 24th week of gestation, eliminating the option of termination in most states.

Similar to a transabdominal CVS, the patient is placed in supine position. An ultrasound survey to assess viability, fetal position, placental location, and a gross anatomic survey is performed before the procedure. Amniotic fluid, 20 to 30 mL, is aspirated into sterile syringes. The amniocytes and desquamated fetal cells floating in the amniotic fluid provide a source of mitotically active cells for cytogenetic evaluation and culture. Levels of AFP and AChE in the amniotic fluid can help identify fetuses at high risk for NTDs. FISH results (see later) are usually available in 2 days, whereas results from cell culture take approximately 7 to 14 days.

The fetal heart rate is assessed and documented after the procedure. It is normal for a patient to experience uterine cramping during the procedure, but cramping should resolve soon after the procedure is over. Patients are encouraged to keep themselves well hydrated and to avoid strenuous physical activity, including intercourse, for 2 days.

Fetal loss is the most devastating potential complication, and the risk attributable to amniocentesis is approximately 1 in 500, although more recent data suggest that it may be even lower.[3] Increased maternal age, a history of bleeding associated with pregnancy, and abnormal serum screening results all increase the risk of fetal loss. Patients are cautioned regarding fetal injury, although this is an extraordinarily rare event with the advent of ultrasound guidance. Leakage of fluid can occur in approximately 1% of cases; however, in contrast to spontaneous rupture of membranes that occurs outside the setting of amniocentesis, 90% are self-limited and resolve spontaneously within 1 week.[10] If a patient reports leakage, a conservative approach—one that monitors amniotic fluid volume, fetal growth, and signs of infection—should be adopted because the prognosis is excellent. Overall, long-term follow-up on offspring of women who had undergone amniocentesis did not show a significantly higher rate of major disabilities compared with matched controls.[8]

Cordocentesis

A third and much more infrequently used modality of diagnostic testing is cordocentesis, also known as *percutaneous umbilical blood sampling*. This procedure involves puncturing the umbilical vein under ultrasound guidance to obtain fetal blood cells for genetic analysis. Usually performed after 18 weeks, the procedure-related pregnancy loss rate is approximately 1 in 100 when the procedure is performed for genetic diagnosis.[24] Given the high loss rate compared with CVS or amniocentesis, use of this test for genetic diagnostic purposes is limited to further evaluation of chromosomal mosaicism discovered on a CVS or amniocentesis result. Instead, most cordocenteses are performed to evaluate and treat fetal anemia, especially in the case of Rh sensitization.

Preimplantation Genetic Diagnosis

Preimplantation genetic diagnosis (PGD) is performed by genetic analysis of a single cell biopsy specimen from an in vitro embryo at the eight-cell stage. Alternatively, polar body biopsy specimens may likewise be obtained before transfer. The nuclear material can be analyzed using molecular or cytogenetic techniques. There is now a wealth of clinical experience using this technology, and it is particularly useful in the assessment of known genetic disorders at the time of preconception. Although some families undergo PGD because of ethical concerns related to termination of pregnancy, some patients choose this approach after having undergone several affected pregnancies because they do not want to take the risk of another untoward and emotionally devastating outcome. Although this technology can also be used to determine whether or not a parent has transmitted a known chromosomal abnormality to his or her offspring, routine screening for aneuploidy remains controversial, and current evidence does not support its use for preimplantation screening of embryos.[29]

The advantage of PGD is that it allows couples to avoid intrauterine transfer of embryos affected by a detectable disorder. The disadvantage is that to perform PGD, a woman must undergo in vitro fertilization (IVF), even if fertility is not an issue, to conceive. PGD does not obviate the risk of fetal structural anomalies as the pregnancy progresses. Infants that are the result of pregnancies with PGD show no difference in the rate of fetal anomalies compared with infants that result from ART alone.[36]

Fetal DNA from Maternal Serum

Cell-free fetal DNA is present in maternal circulation throughout pregnancy. Examination of this DNA has resulted in determination of fetal rhesus D (RhD) status, gender, and the presence or absence of aneuploidy. At this time, this technique is not reliable or efficient for wide clinical use, however. The idea of noninvasive fetal genetic screening is very appealing, and ongoing research is likely to result in more refined use of cell-free fetal DNA in the future.[23]

TECHNICAL ADVANCES IN MOLECULAR CYTOGENETICS

Molecular and cytogenetic diagnostics are an important part of genetic counseling. Increasing understanding of the human genome has led to the development of efficient, accurate testing modalities. Following is an overview of the most commonly used diagnostic tools.

Chromosomal analysis, or karyotyping, is best performed when the cell is in prometaphase or metaphase and the chromosomes are condensed. The most common staining technique, a Giemsa stain, results in a distinct pattern of alternating light and dark bands that is dependent on the composition of the underlying DNA sequence. Each chromosome has a unique banding pattern. Analysis of this banding pattern can show structural abnormalities. The disadvantage of this technique is that the sensitivity of banding is limited, which means that small structural abnormalities or mutations would go undiagnosed. The advantage of this technique is that the whole genome is visualized at one time.

FISH is a diagnostic tool that has better resolution than traditional chromosomal banding. After denaturation, a DNA probe labeled with a fluorochrome is directly hybridized onto cells that have been fixed onto a glass slide. The fluorescent signal is immediately visible by fluorescence microscopy. A double signal corresponds to one signal on each chromosome pair. Cells with one nuclear signal are monosomic for the chromosomal region being evaluated. Conversely, trisomic cells have three nuclear signals.

The advantage of FISH is that it can be applied to nondividing and dividing cells. It can identify several different types of mutations—deletions, duplications, and aneuploidy. Its major disadvantage is that structural abnormalities are missed because the DNA probe detects only the presence of a genetic sequence, not its location. Although FISH is a rapid test, its use is currently limited to a few aneuploidy and deletion syndromes. FISH is an important tool for patient care in labor and delivery and the neonatal intensive care unit when quick decision making is required. Because of its limitations, however, a full karyotype is still performed before formulating a definitive report.

Polymerase chain reaction (PCR) is a process to amplify a single DNA molecule into thousands of copies in a matter of hours. The double-stranded DNA of interest is heated to separate into two single strands. Single-stranded primers, usually 20 to 30 nucleotides in length, are mixed in to allow them to anneal to the opposite DNA strands of the desired target. Next, a thermostable DNA polymerase and single nucleotides are introduced, and the complementary strand is synthesized using the primers as sites of initiation.

The advantage of PCR is that it is fast and extremely sensitive, meaning that PCR can amplify DNA from a single cell. Because of this sensitivity, however, contamination with even small amounts of other DNA can produce an erroneous result. To design appropriate primers, the nucleotide sequence information of the target region must be known.

Quantitative PCR is a newer application of standard PCR in which the accumulation of PCR products over time is measured directly with the use of fluorescent probes that hybridize to the target sequence. This probe begins to fluoresce when the DNA polymerase cleaves it. The fluorescent signal increases proportionally to the amount of PCR product, and this signal is quantified by comparing the cycle number at which the sample reaches a predetermined level of fluorescence with a standardized curve of a control. In some countries, this technique is preferred over FISH analysis.[19]

Duplications or deletions that are too small to see by chromosomal banding can still have important clinical sequelae. These small changes can be detected by comparative genomic hybridization. This technique measures the differences in copy number, or dosage, of DNA segments being evaluated. Labeled control and sample DNA should fluoresce in a 1:1 ratio. If the sample DNA has a deletion, this ratio of sample to control changes to 0.5:1. In addition to prenatal diagnosis, comparative genomic hybridization has applications in pediatric diagnosis.

Although this technology holds great promise in reaching the goal of rapid, high-resolution cytogenetic evaluation, an area of concern is how to interpret copy number variants. In humans, the amount of variability can cause difficulty in interpretation of results, particularly when using oligoarray technology. Determining the significance of copy number variants would be an important development in the use of this promising technology.[35]

ASSISTED REPRODUCTIVE TECHNOLOGIES

More than 40,000 infants born in the United States each year are conceived through ART. The outcomes of techniques such as IVF and intracytoplasmic sperm injection have been well examined. The risks of ART can be divided into two categories—obstetric risks and fetal risks.

Thirty percent of ART pregnancies are twins or higher order multiples, which inherently carries an increased risk of premature delivery. Singleton IVF pregnancies are also at an increased risk of preterm delivery, a twofold risk, compared with spontaneously conceived singleton pregnancies. IVF singleton pregnancies also have increased risk for other morbidities, including abnormal placentation, preeclampsia, and cesarean delivery.[31]

Fetal risks when comparing IVF singletons versus spontaneous conception singletons include low birthweight, intrauterine fetal demise, and cerebral palsy.[31] All these risks are approximately twice baseline risk. Large population-based studies revealed that the adjusted odds ratio for major congenital malformations for IVF fetuses was 1.3. Chromosomal abnormalities when adjusting for maternal age are similar between IVF and spontaneous conceptions.[18] The risk of de novo chromosomal abnormalities seems to triple, however, if intracytoplasmic sperm injection is performed. It has been observed that pregnancies that are the result of ART are at an increased risk for rare imprinting disorders, such as Beckwith-Wiedemann syndrome, suggesting that epigenetic changes may occur as a result of ART.[17,38]

Although there may be increased morbidity related to ART, there is still no clear evidence as to whether these issues are related to the procedure or to the underlying cause of infertility, as there can never be a true control group of children who were born to infertile couples who did not undergo ART. In other words, there are two important considerations in this regard—the impact of gamete manipulation and the inherent characteristics of the infertile population itself on pregnancy outcome. Handling of oocytes or embryos during critical periods of development could affect important processes. The average maternal age at time of conception with ART is higher than spontaneous conceptions. Male patients with infertility who require intracytoplasmic sperm injection have an increased incidence of genetic abnormalities themselves. Future studies to clarify the role of each of these considerations will be important in clearly defining the risks to the developing fetus.

GENETIC EVALUATION AND COUNSELING

Genetic counseling is an ever-evolving field that has become an important part of clinical practice. Full of ethical and practical challenges, genetic counseling focuses on assessing a patient's genetic risk to provide individualized information and options. Some level of genetic counseling is provided by health care professionals in all fields of medicine. Obstetricians spend time with their pregnant patients discussing prenatal screening and diagnosis, whereas oncologists review hereditary cancer susceptibility. Patients can also be referred to genetic counselors, formally trained professionals who have received a Master's level degree and are certified by the American Board of Genetic Counseling. Genetic counselors are trained not only in pedigree construction and analysis, but also in communication education and counseling skills, and are a distinct discipline from medical geneticists, who are certified by the American Board of Medical Genetics after completing a residency program. Although such physicians also provide counseling, their focus is more on diagnosis, treatment, and management of genetic disease.

In many centers, physicians and counselors work as a team to provide comprehensive genetic services. Indications for referral are varied, but include (1) family history of early-onset cancer, (2) personal or family history of known or suspected hereditary disease, (3) ethnic background associated with an increased risk of a heritable disorder, (4) teratogen exposure during pregnancy, (5) abnormal prenatal ultrasound or abnormal first-trimester or second-trimester screening results, and (6) recurrent pregnancy loss. Any pregnancy at risk of birth defects warrants such a referral.

A genetic counseling visit entails obtaining a detailed medical and family history, including the age and health status of first-degree, second-degree, and third-degree relatives. For the prenatal patient, additional information such as genetic screening results, ultrasound findings, and possible teratogenic exposures is discussed. This information allows for a targeted discussion regarding the likelihood of developing disease, testing options for the condition, the impact that an illness could have on the patient and family, and the possible interventions available to modify the disease.

Ideally, genetic counseling is provided in a nondirective manner; emphasis is placed on educating the patient on his or her options and the consequences of those options. Before initiating any testing, a provider should ensure that proper consent is obtained. It is up to the provider to ensure that the patient understands the nature of the test, its limitations, and its potential sequelae. This becomes more complex when testing children or adolescents is considered. In this situation, the benefits of timely genetic testing should be the primary justification. The American Society of Human Genetics (ASHG) suggests that "counseling and communication with the child and family about genetic testing should include advocacy on behalf of the interests of the child."[7] Generally, if there is no immediate benefit to the child, testing is usually deferred until adulthood, when the individual can make his or her own choices.[7]

Another ethical dilemma of genetic testing that clinicians face is the balance between maintaining patient confidentiality versus the duty to protect other family members who might be affected. An individual's genetic testing results have implications for an entire family. The ASHG encourages voluntary disclosure by the person tested (proband) whenever possible. If this does not happen, the ASHG recommends that the degree of disclosure to other family members depends on the magnitude and immediacy of risk faced, stating that disclosure is acceptable if "harm is likely to occur, and is serious, immediate, and foreseeable."[3]

A concern that many patients have is the impact on their genetic testing results on future employment and ability to obtain health insurance. In 1995, the Equal Employment Opportunity Commission issued guidelines that individuals discriminated against based on their genetic testing had the right to sue. A year later, the Health Insurance Portability and Accountability Act (HIPAA) was enacted to prevent insurance companies from denying coverage based on genetic testing. On a federal level, the Genetic Information Nondiscrimination Act (GINA) was passed in early 2008.[43] It prohibits U.S. insurance companies and employers from discriminating on the basis of information derived from genetic tests. Insurers and employers are not allowed under law to request or demand a genetic test. GINA prevents insurance companies from discriminating through reduced coverage, and prohibits employers from making employment decisions based on an individual's genetic code. State laws that have an impact on the provision of genetic services also exist, and there may still be issues with respect to procurement of life insurance despite the aforementioned laws.

CONCLUSION

An understanding of the genetic basis of disease and the tools available for prenatal genetic evaluation is vital in the management of patients and their offspring in the peripartum and newborn period. Reproductive genetic counseling and diagnostic techniques are a vital means of defining a potential clinical dilemma, allowing for seamless coordination between obstetricians and neonatologists. Medical genetics is a rapidly evolving field with new advances and discoveries reported frequently. The underlying genetic core principles and the clinician's respect for patient autonomy to make good choices based on complete information have remained unchanged, however.

CHAPTER 9

Perinatal Imaging

Nancy E. Judge, Stuart C. Morrison, and Noam Lazebnik

Ultrasound has permanently changed the image of perinatology, increasing expectations and improving outcomes in neonatal care. In the past decade, sonographic genetic screening, Doppler vascular measurements, and three-dimensional examinations have moved from investigational techniques to widely accepted diagnostic tools. Gradually, the field of obstetric ultrasound (US) has matured, establishing its relevance and its limitations in antenatal diagnosis. Most recently, magnetic resonance imaging (MRI) has joined sonography for the prenatal diagnosis of an ever broader spectrum of disorders.

FETAL IMAGING TECHNIQUES

Real-time ultrasound, in which image brightness varies with the intensity of returning signals (B-mode), is the standard method of fetal imaging (Fig. 9-1). Typically, brief signal bursts are followed by relatively long receptive intervals; lower signal frequencies encounter less interference but reflect from fewer informative interfaces. Image quality varies with distance to the target, structure size, movement relative to the signal, and tissue transmission characteristics. Ideally, the transducer is in proximity to its target; transvaginal scans facilitate gynecologic examinations and early gestation and cervical studies. Suboptimal images are common with obesity, limited fluid interfaces, intervening structures, and poor positioning with respect to the beam. Diagnostic difficulty also increases when different materials have similar echo characteristics, such as blood, urine, and ascites.

M-mode ultrasound is a direct representation of beam reflection by moving edges (e.g., in cardiovascular imaging). Interpretation requires hard-to-achieve, standardized stable views; fetal M-mode imaging has been deemphasized because of improved B-mode resolution. M-mode is useful in assessing arrhythmia, contractility, and pericardial effusion. M-mode “snapshots” also document cardiac activity and rate (Fig. 9-2).

Doppler ultrasound uses the frequency shift that occurs when the beam is reflected off moving objects to demonstrate the presence, velocity, and direction of blood flow. Pulsed waves are used to determine flow velocity from individual vessels (Fig. 9-3). Direct volume calculations from narrow, tortuous fetal and uterine vessels are inaccurate. To compensate, prenatal Doppler findings, ideally obtained at beam angles less than 60 degrees, are generally expressed as ratios.

Color Doppler ultrasound semiquantitatively assigns direction to flow; by convention, warm colors denote movement toward the transducer, and saturation is keyed to velocity. Color Doppler illuminates cardiac, arterial, and venous structures (Figs. 9-4 and 9-5); any moving structure is potentially amenable to color Doppler detection. Color Doppler energy (power Doppler) is based on signal intensity; amplitude corresponds to blood cell motion. Color Doppler is effectively independent of angulation and is sensitive to very low flow, thus it is helpful for mapping vascular beds and for quickly spotting umbilical, pulmonary, middle cerebral, pericallosal, and other vessels (Figs. 9-6 and 9-7).

Three-dimensional ultrasound (US) acquires and analyzes returning echoes along a third axis. Images are then manipulated electronically to show both surfaces and volumes from multiple perspectives, both as static and real-time (four-dimensional) views. Surface rendering of subtle facial details and of fetal small parts, multiplanar views, and stratified slices enhance detection of anomalies and partly overcome positional limitations of standard scans (Fig. 9-8). Three-dimensional studies have facilitated volume calculations, analysis of complex spatial relationships, and have better explicated abnormal findings.[9] Spatiotemporal correlation of heart movement with color and power Doppler augments standard cardiac imaging (Fig. 9-9). Skilled practitioners report significant gains in efficiency by off-line interpretation of acquired volumes in lieu of real-time scanning.[8] Three-dimensional data sets are likely to become a standard format for research, remote interpretation, and consultative purposes. Post hoc analysis of stored volumes during litigation might also be expected. Three-dimensional studies can be significantly hampered by artifacts and erratic resolution, memory-intensive archival requirements, and inherent dependence on two-dimensional signal quality.

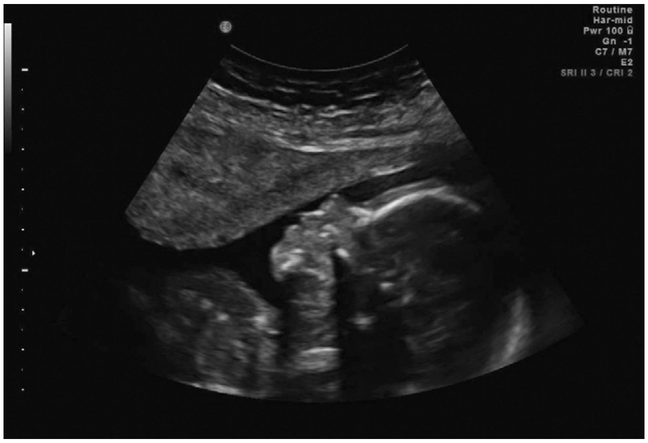

Figure 9–1. Transabdominal B-mode, two-dimensional scan. Profile of 20-week fetus.

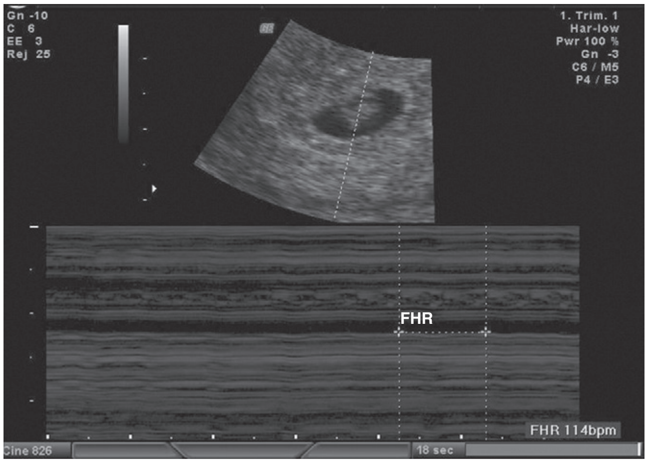

Figure 9–2. Transvaginal M-mode demonstration of embryonic cardiac activity at 5 5/7 weeks' gestation. Upper frame: Embryo with cursor across thorax. Lower frame: M-mode display of wall movement during two cardiac cycles, 114 beats per minute (between vertical lines).

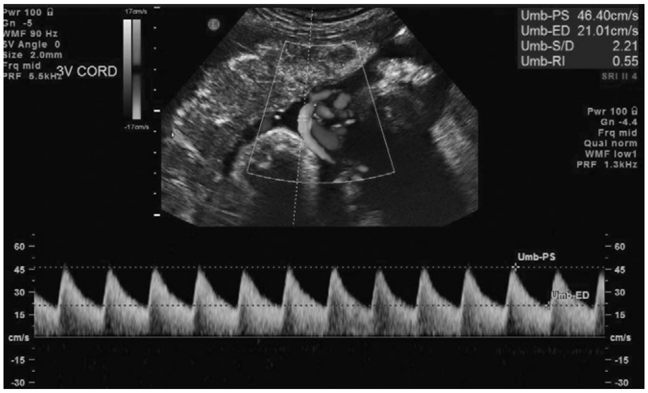

Figure 9–3. Upper frame: Color Doppler highlights a loop of umbilical cord (trapezoid). The gate (transverse parallel lines) identifies the sampling site within the umbilical artery. Lower frame: Pulse Doppler waveform recorded from the umbilical artery (see Fig. 9-4). See color insert.

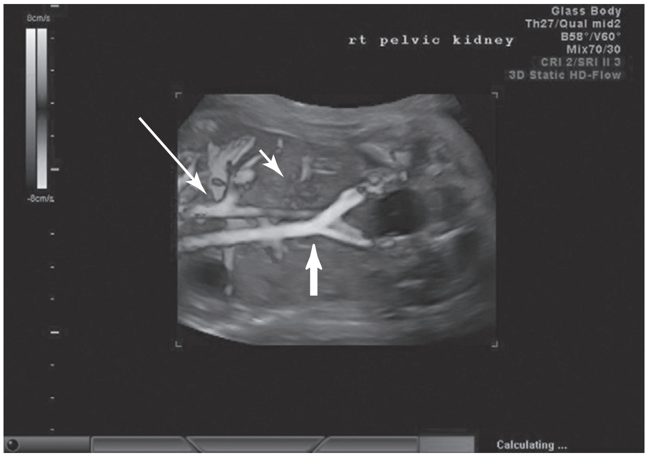

Figure 9–4. Color flow Doppler demonstration of a right pelvic kidney *(long arrow)*, descending aorta *(thick arrow)*, and inferior vena cava *(short arrow)* in a 28-week fetus. Flow toward the transducer is the color of the upper bar; flow away corresponds to the lower bar colors. See color insert.

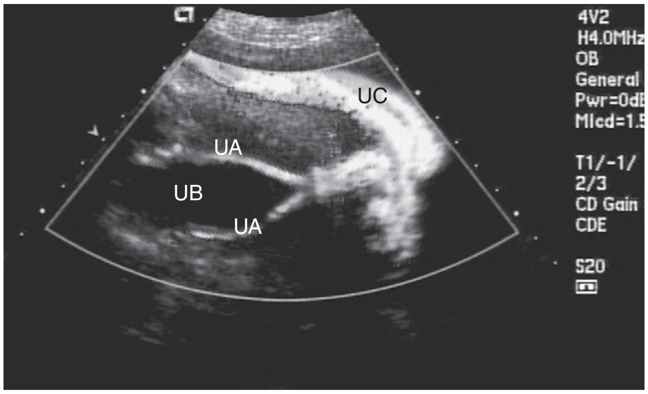

Figure 9–5. Transverse view of fetal pelvis, umbilical cord (UC), and urinary bladder (UB) with power Doppler showing bifurcation of the umbilical arteries (UA).

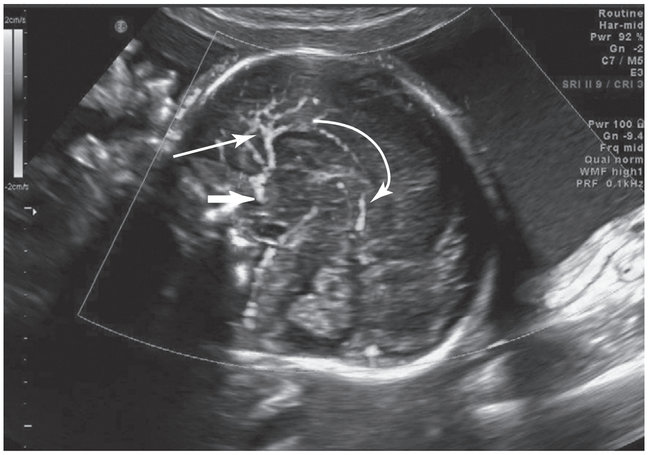

Figure 9–6. Color Doppler demonstration of the internal carotid, middle cerebral, and pericallosal arteries (*thick*, *thin*, and *curved arrows*). Lower velocities are shown as more saturated hues. Turbulent flow and flow more rapid than the scale parameters demonstrate aliasing (mixture of colors). Compare with Figure 9-7, power Doppler of same structures. See color insert.

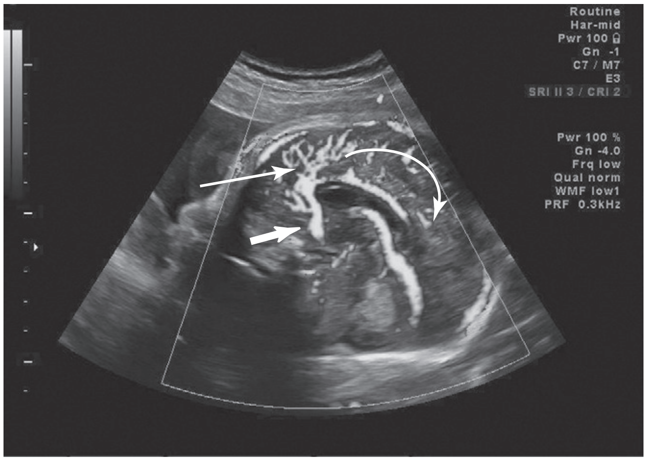

Figure 9–7. Power Doppler parasagittal cranial image of internal carotid *(short thick arrow)*, middle cerebral *(long arrow)*, and pericallosal arteries *(curved arrow)*. See color insert.

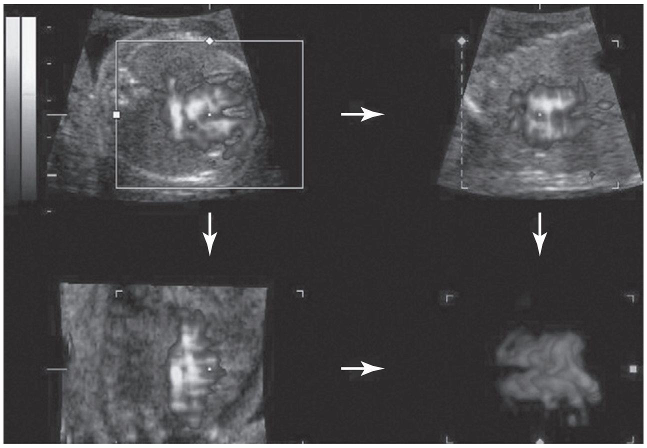

Figure 9–9. Spatiotemporal color flow imaging of normal four-chamber heart at 18 weeks. Transverse chest with four-chamber view. Upper left: Cardiac apex facing right. Upper right: Axial view. Lower left: Coronal view. Lower right: Cardiac apex facing left (three-dimensional). See color insert.

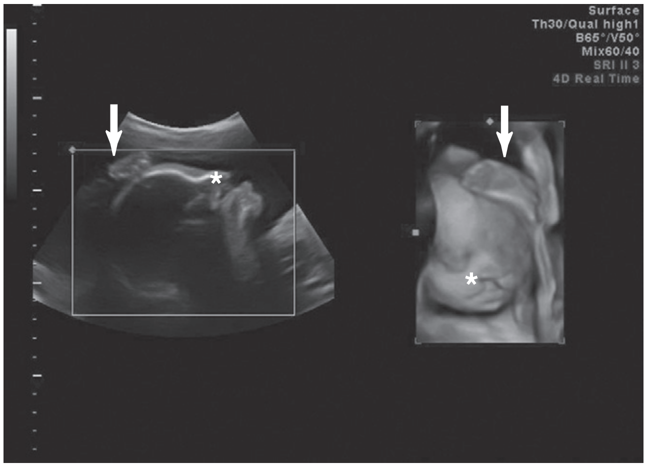

Figure 9–8. Two-dimensional profile (compare with normal profile in Fig. 9-1) and three-dimensional coronal rendering of a 26-week fetus with a large, right-sided cleft lip and palate *(asterisk)*. The fetus is in a frank breech position with the foot *(arrow)* visible on the head. See color insert.

MRI can now be performed quickly, usually eliminating the need for maternal or fetal sedation. Maternal oblique positioning prevents inferior vena caval compression. Each image is obtained with an ultrafast sequence in less than 1 second. Individually tailored to specific problems or anatomic areas, MRI is not used for comprehensive screening, unlike ultrasound. The large field of view, excellent soft tissue contrast, and multiple planes of construction make MRI an appealing imaging modality. MRI can supplement ultrasounds limited by maternal obesity or oligohydramnios. MRI is usually used in the second and third trimesters to elucidate problems found on earlier ultrasound examinations. Fast T2-weighted sequences with single-shot fast spin-echo techniques are the most commonly performed sequences. Images are acquired in the axial, coronal, and sagittal planes to the fetus or orthogonal to the maternal pelvis. T1-weighted sequences detect recent hemorrhage and meconium-filled bowel. Diffusion imaging is useful for identifying ischemic injury to the brain. The use of gadolinium is relatively contraindicated but may be justified for assessment of placental accretion or serious maternal disease. Claustrophobia can be difficult for some patients.

BIOEFFECTS AND SAFETY

Most pregnant women with access to modern obstetric care undergo sonographic examinations during the first and later trimesters. There has been no convincing evidence of harm in humans to date,[2] although the endemic nature of early ultrasound exposure in modern obstetrics may require ingenuity in future study designs. By definition, ultrasound is inaudible; however, sound energy can produce both heat and pressure effects in tissue. Although not oncogenic, under nonclinical conditions, ultrasound may cause cell lysis, intracellular shearing, streaming effects, altered membrane permeability, and abnormal chromosome function. Small mammals experience smaller litters, impaired growth, and more anomalies after in utero exposures that do not always exceed comparable human levels. Current energy outputs greatly exceed those used in most of the original safety studies, with particular concern aimed at energy output during embryogenesis. Heat exposure triples with each change in modality: from B-mode and three-dimensional, to M-mode, to color flow, before peaking during pulse Doppler. Harmful levels should not be reached during routine studies, but might occur during focal cranial Doppler interrogation or in a febrile patient, without unusually long exposures.[1] Mechanical disruption from cavitating gas bubbles is improbable in the fetus. Both temperature and disruption risks are displayed on equipment (Fig. 9-10); thermal index (TI) is a ratio between transducer output and the energy needed to warm tissue 1°C, with a desired value less than 2. Thermal index is further categorized by tissue type: soft tissues, cranial structures, and bone. Mechanical index (MI) refers to pulse amplitude tissue effects of compression and decompression, ideally maintained below

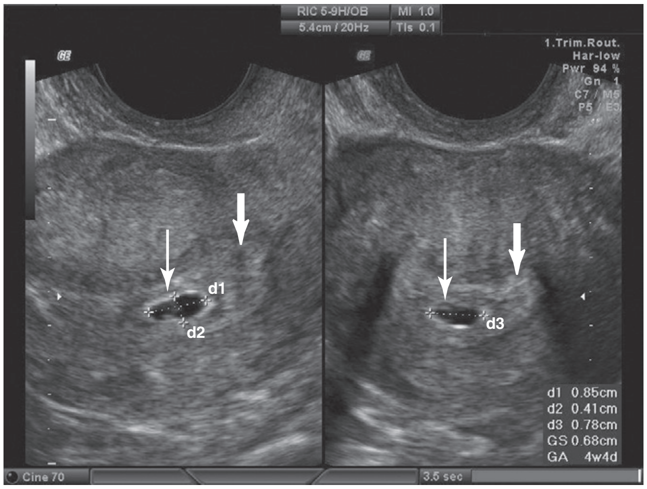

Figure 9–10. Transvaginal longitudinal and transverse axis ultrasound images of a 4 4/7-week intrauterine pregnancy, showing a small yolk sac *(thin arrows)* within the gestational sac (calipers) and echogenic surrounding dicidual reaction *(thick arrows)*. The embryo is not yet visible. Note MI and TI notations at top center.

0.4 in fetal studies.[1] These levels may be exceeded by practitioners trying to achieve interpretable images during early gestation or in obese and other difficult to scan patients. For safety, only medically essential examinations should be performed; settings and duration should be the minimum required to achieve adequate views.[5]

MRI uses strong magnetic fields and radiofrequency waves with no known harmful biologic effects, but large longitudinal studies are lacking. As with ultrasound, heat delivery to the fetus is a recognized hazard; in MRI, however, the maternal surface receives the greatest thermal exposure. Noise from the coils (up to 120 dB) is capable of causing acute hearing damage; tissue attenuation decreases fetal intensities by 25%, to relatively safe levels. Direct magnetic bioeffects remain unproven; the FDA[45] states that safety to the fetus "has not been established."

ETHICAL CONSIDERATIONS

The education of physician sonologists encompasses visual recognition and interpretative tasks common to diagnostic imaging, but also demands mastery of specific mechanical skills (or at least an ability to assess the latter in sonographers). Ultrasound is an abbreviated module in general radiology and obstetric training with proportionate underrepresentation on certification examinations. Graduates may be obliged to acquire experience in the field to an undesirable degree, given the realities of medical practice and the serious consequences of error. Both US and MRI are rapidly evolving; clinically relevant frontiers are often explored by collaborative fields that benefit from pooled data, prerelease technology, and funding for staff and statistical analysis. Laudable advice from these investigators to confirm applicability or to undergo formal training before adopting practices may be deemed unrealistic or self-serving by readers with fewer resources. Nuchal translucency (NT), a deceptively simple method for aneuploidy screening, sounds a cautionary note (Fig. 9-11).[44] Despite orderly dissemination, certification courses, ongoing audits, professional society support, and laboratory coordination, in contrast to the near-viral dissemination of many advances, reliability remains a concern, complicating accuracy and counseling. Practitioners should be candid when informing patients of their ability to provide a requested service and assiduous in improving their skills. Professional judgment remains paramount in deciding how and when to incorporate new developments into clinical practice.

Prenatal identification of fetal sex for the purpose of selective termination is available for serious X-linked disorders, but has been more widely applied to abort normal females because of a lower perceived value (Fig. 9-12). No fully satisfactory response, whether acquiescence, nondisclosure, or noninspection, has been found for this abhorrent societal bias.[25]

Multiple gestations may result in a number of dilemmas. Advances and regulation in assisted reproductive technology (ART) have decreased the incidence of multifetal pregnancies, but fetal reduction remains a painful choice for parents

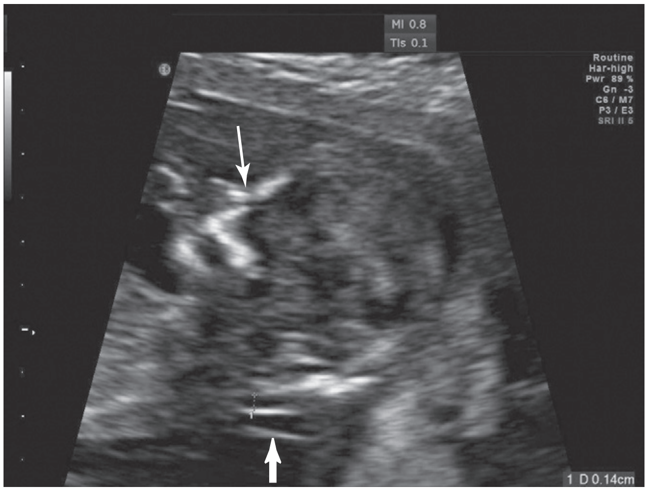

Figure 9–11. Nuchal lucency measurement (calipers) in a 13-week fetus. The nasal bone is visible *(thin arrow)* and the amnion *(thick arrow)* is clearly distinguished from the skin fold. Note TI and MI settings are displayed on this image.

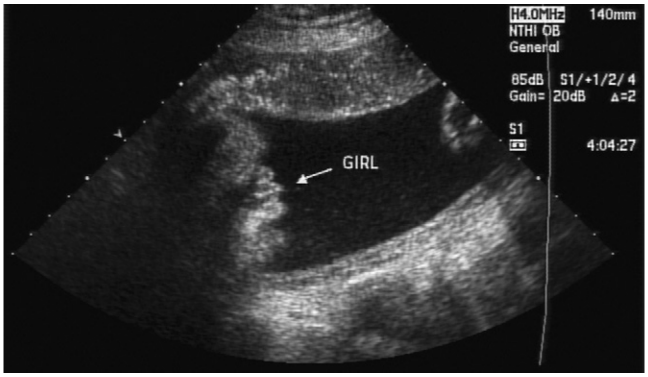

Figure 9–12. Vulvar skin folds *(arrow)* of normal female fetus in the midtrimester.

facing the prospect of extreme prematurity in higher order multiples. The management of twin-twin transfusion syndrome, anomalous co-twins, and discordant growth or distress far from term necessitate choosing among unsatisfactory options.

Nondiagnostic studies for a suspected diagnosis, varying prognoses for a given diagnosis, and the inherent limitations of US and MRI lead to ethical issues in management and counseling. Physicians and patients both share unrealistic expectations for the predictive accuracy of targeted diagnoses.[27] Anomalies and variants linked to Down and other syndromes (“markers”) discovered during routine studies present patients and caregivers with unanticipated, unwelcome choices, particularly if patients explicitly refused serum screening or direct genetic testing.[23] Ideally, an informed consent discussion that addresses risks, benefits, consequences, and limitations of US or MRI should be provided by the referring clinician to all patients before they choose to undergo such imaging.[34] Given the irreversible nature of birth and abortion, ultimately prospective parents must judge for themselves their tolerance for uncertainty in diagnosis and for imperfection in their offspring.

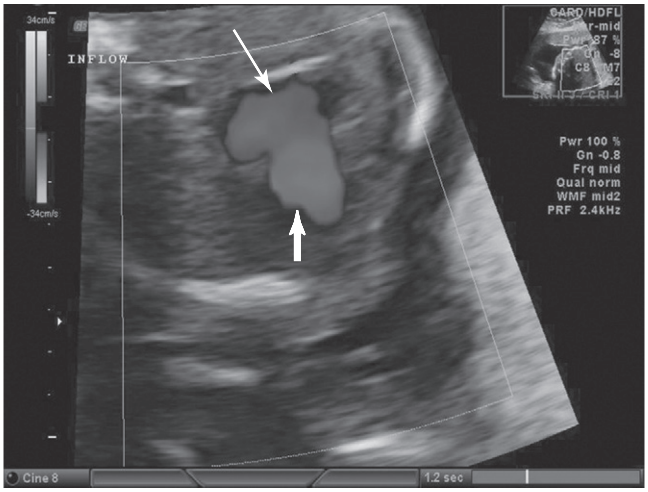

Figure 9–13. Fetus with trisomy 21 and large atrioventricular canal defect, transverse thorax. Without the presence of a normal crux, color flow shows flow from a common atrium *(thin arrow)* into a common ventricle *(thick arrow)*. See color insert.

APPLICATIONS OF ULTRASOUND

Genetic Screening

Genetic screening combines ultrasound and biochemical testing to enhance the detection of chromosomal abnormalities, resulting in greater scrutiny of younger patients and less frequent invasive testing for women older than 35 years (see Chapter 8).[4] Different algorithms yield noticeable variations in sensitivity, specificity, and predictive values; cost or convenience may factor in choosing a strategy.[21] At least one third of fetuses with Down syndrome will have anomalies, notably endocardial cushion defects (Fig. 9-13), duodenal atresia (Fig. 9-14), and less detectably, small atrioseptal and ventriculoseptal cardiac defects (Fig. 9-15). Two thirds may have associated markers, not limited to increased nuchal lucency and hypoplastic nasal bones in the first trimester; thickened nuchal fold (Fig. 9-16) and nasal hypoplasia; ventriculomegaly; choroid cysts (Fig. 9-17); hypoplasia of the fifth digit, decreased long bone to biparietal diameter ratios, enhanced echogenicity of papillary muscles and bowel, and renal pyelectasis (Fig. 9-18) reported in the second trimester. Screen components may be affected by ethnicity, habitus, build, diet, and fetal sex, as well as by operator-dependent detection rates. The permutations stymie counselors attempting to provide (and patients trying to grasp) basic descriptions of risks and benefits. Doppler documentation of tricuspid regurgitancy and increased ductus venosus resistance in the first trimester seems a promising addition to early screening protocols, but raises concern about the effects of exposures required to obtain optimal views.

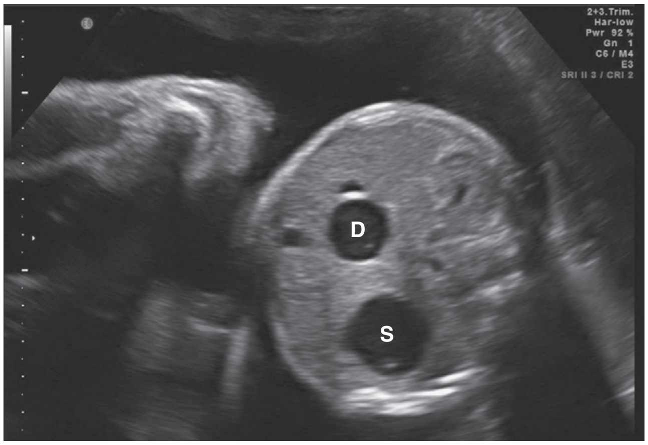

Figure 9–14. “Double bubble” sign of duodenal atresia in a 35-week pregnancy, with the dilated stomach (S) and the obstructed proximal duodenum (D) seen on transverse abdominal view, spine to right of image. The finding is uncommon before the late second trimester.

Assisted Reproduction

Ultrasound is essential for timing and guiding egg retrieval and helpful in embryo transfer; its role in judging endometrial receptivity is less clear. ART results in more twins and higher-order multiples; early US of embryos, amnionicity, and chorionicity is essential to subsequent management. ART patients also risk ectopic and heterotopic pregnancies at more than double the usual rates. US rapidly identifies abnormal implantations, often allowing for medical or minimally invasive therapy, and guides care of hyperstimulation. Assignment of color to three-dimensional follicle scans promises to speed enumeration of follicles (Fig. 9-19). Saline US studies routinely complement or replace hysterosalpingograms in assessment of uteri and adnexa. MRI may play an expanded role in structural and functional evaluation in the future.

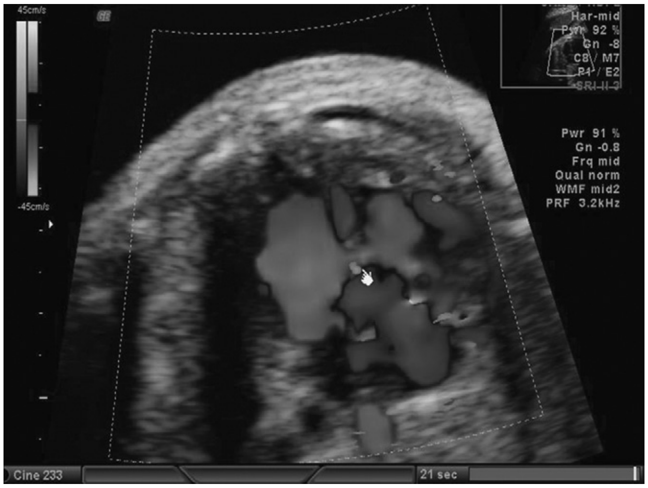

Figure 9–15. Ventriculoseptal defect *(pointing finger)* demonstrated by color flow Doppler in 28-week fetus. See color insert.

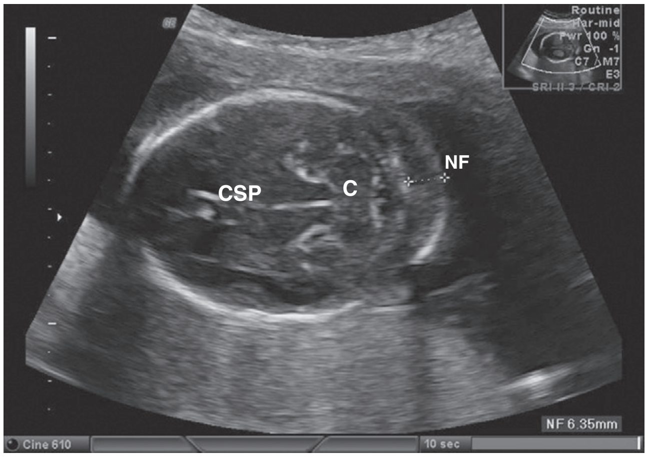

Figure 9–16. Thickened nuchal fold (NF) calipers at a level demarcated by the cavum septum pellucidum (CSP) and the cerebellum (C), here noted at 18 weeks, is considered a marker for trisomy 21 (Down syndrome) and cardiac and other anomalies. The finding is infrequent, even in affected infants, limiting its utility.

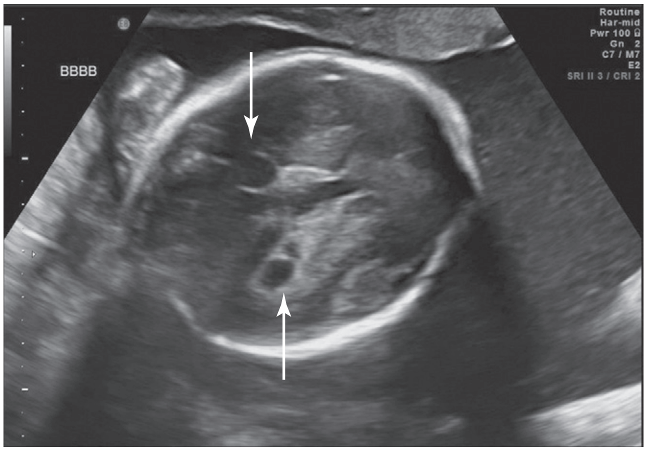

Figure 9–17. Choroid plexus cysts. Coronal view of the brain shows bilateral choroid plexus cysts *(arrows)*.

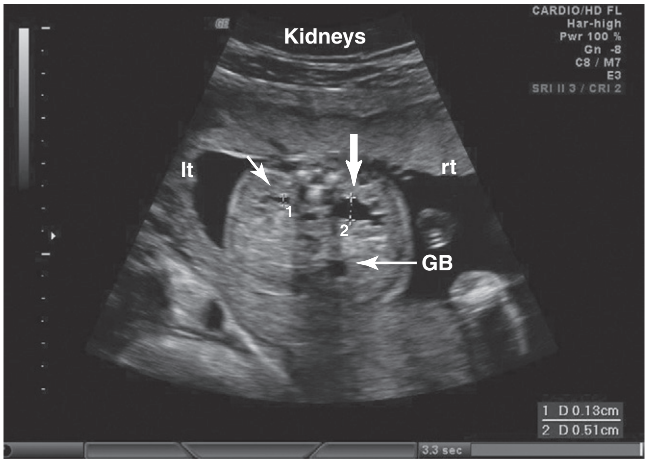

Figure 9–18. Transverse abdominal view, backup. Gallbladder, (*arrow* GB) at right, with asymmetric renal pelves (calipers) illustrating the normal left renal appearance *(short thin arrow)* and right pyelectasis/caliectasis *(thick arrow)*. Between 1% and 5% of normal fetuses have pyelectasis, limiting its utility as an isolated marker.

First-Trimester Studies

Traditionally, first-trimester transvaginal scans exclude ectopic implantations and confirm viability by demonstrating an intrauterine "double sac," yolk sac, and embryo with cardiac activity; identifiable embryos in the salpinx are uncommon. Heterotopic pregnancy (coexisting intrauterine and extrauterine implantation) occurs in less than 0.1% of patients, leading to the pragmatic approach that finding an intrauterine pregnancy usually excludes an ectopic.[7] A "double sac" is usually seen transvaginally at levels of 1000 to 1500 international units of human chorionic gonadotropin before 5 1/2 menstrual weeks (see Fig. 9-10). Finding the yolk sac confirms the intrauterine site. The gestational sac diameter grows 1 mm daily in early pregnancy, and the embryonic disc should be visible once sac diameters exceed 15 mm. The maximum embryonic length also increases by 1 mm daily; transvaginal documentation of cardiac activity is expected by the end of the sixth week (4 mm embryonic length).[32] Embryonic heart rates increase to more than 160 beats per minute by the ninth week and then decline slightly through the 13th week. Persistent rates less than 100 beats per minute are often linked with abortion, aneuploidy, and anomalies.[22] Embryonic surveys are limited and necessarily provisional; early fetal period scans can diagnose a number of entities accurately (Fig. 9-20). Midtrimester confirmation continues to be prudent for the majority of first trimester findings. Later studies retain advantages with respect to the natural history of many anomalies and for visualization of heart, spine, and other problematic structures.

Multiple Gestation

(See also Chapter 19.)

With an increase in the number of fetuses, scans become more complex, time consuming, and error prone; additionally, determination of zygosity is an essential element of the study. The management of anomalous, discordant, or moribund

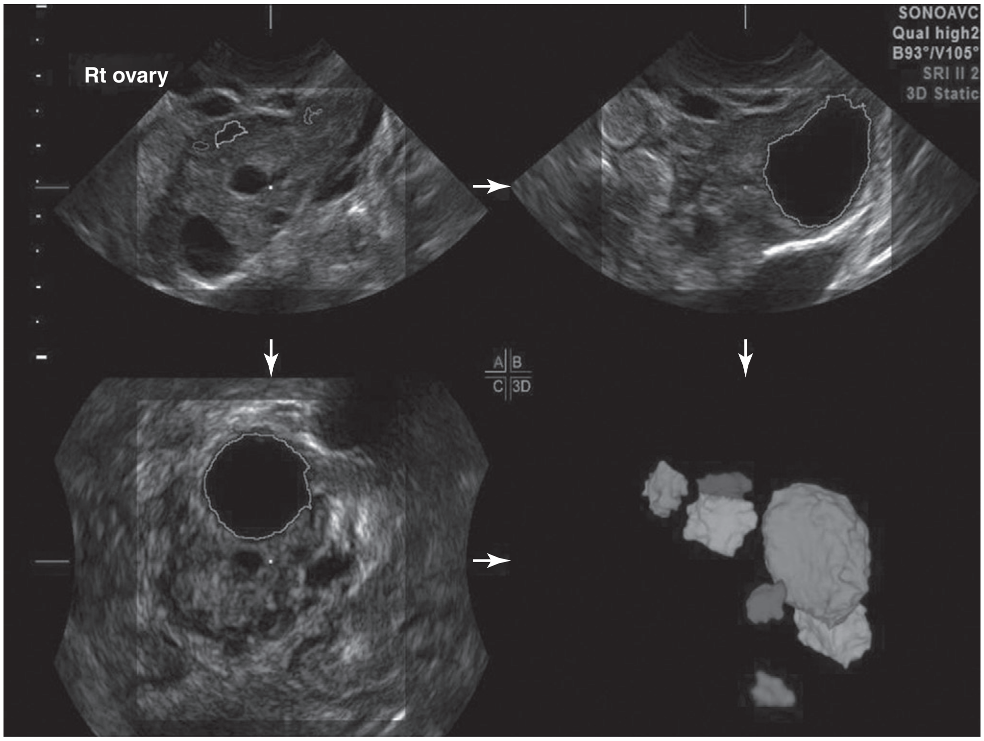

Figure 9–19. Three-dimensional color-enhanced volume rendering of seven follicles in the right ovary. The echo-free follicles are outlined by the operator in orthogonal planes. The generated volumes are then displayed in the three-dimensional rendering (lower right) with color correlation. See color insert.

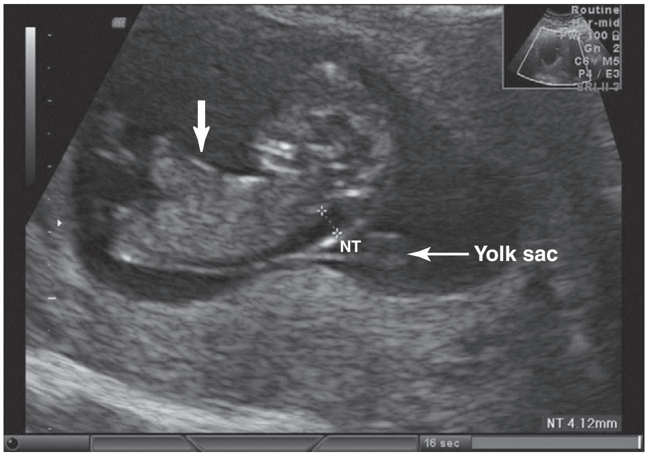

Figure 9–20. Eleven-week embryo with a thickened nuchal lucency and an omphalocele *(thick arrow)* containing fetal liver. The fetal liver does not undergo physiologic herniation. A study at 18 weeks identified a lumbosacral spina bifida in addition to confirming the omphalocele.

co-twins differs significantly based on chorionicity (Fig. 9-21). US categorization is most accurate for different-sexed twins, but approaches this accuracy in gender concordant pairs by assigning chorionicity based on sac appearance in early gestation. Successful attempts may be made throughout gestation by examining the dividing membranes at their placental origin. Dichorionic diamniotic twins are usually dizygotic, with independent risks for anomalies and placental malfunction. Monochorionic pairs are predictably monozygotic; attrition rates exceed 30% from early abortion, anomalies, and prematurity. Matched and isolated anomalies are both common in monochorionic gestations; loss of a co-twin may kill its sibling outright or produce neurologic damage in up to one third of survivors. Monochorionic twin-twin transfusion syndrome (TTTS), more common in females, is characterized by unbalanced, shared perfusion that restricts growth and amniotic fluid production in the donor and causes volume overload, cardiac dysfunction, and polyhydramnios in the recipient. Ultrasound staging has been used to time and to guide a variety of ablation strategies. Serial amniocentesis may be helpful in milder cases. Management by these approaches has been modestly effective in decreasing stillbirths and prematurity in TTTS. Monoamniotic twins rarely experience TTTS but have cord entanglements, almost half of which are lethal. Carriage to term and labor are usually avoided in this type of twinning. For all multiple gestations, serial US monitoring to assess growth, well-being, placental performance, and cervical length is common practice.

PREGNANCY EVALUATION

More than 50 fetal structures have now been measured by US, with results expressed as a function of gestational age. Commercial equipment comes with a variety of preinstalled nomograms and biometry-based dating and weight estimation algorithms. These should be reviewed for study limitations and population characteristics before using in place of user-specific curves. Biometry can evaluate the size and development of structures given sure dating, but one of the most powerful applications of prenatal US is using biometrics to establish or confirm gestational age.[14] Through 22 weeks of gestation, most genetically normal individuals cluster closely on nomographic curves.[18] If accelerated or restricted growth supervenes, ultrasound dating is compromised accordingly.

One of the first dating parameters developed was the biparietal diameter (BPD), obtainable after parietal bone calcification

in week 12. Biparietal diameter is measured from the outer to the inner table of the skull, perpendicular to the parietal bones and central falx cerebri. The proper plane contains the cavum septum pellucidum, thalami, third ventricle, and tentorial hiatus, in conjunction with the bony table head circumference (Fig. 9-22). Biparietal diameter and head circumference are relatively spared in nutritional and perfusional disorders of growth; cranial measurements may be distorted by compression. The abdominal circumference (AC), measured along the outer margin of the abdominal skin line at the level of the gastric bubble and the intrahepatic portion of the umbilical vein at the bifurcation of the portal veins, is the best single predictor of growth aberrations but is less helpful for dating (Fig. 9-23).

Figure 9–23. The abdominal circumference indirectly reflects hepatic glycogen stores. The correct level should include the gastric bubble *(thin arrow)* and the junction of the portal veins *(thick arrow)*; the circumference should be fitted to the outer diameter of the skin line.

Femoral length is the fourth measurement commonly included in biometric formulae. Extraocular and transcerebellar diameters, and humeral and pedal lengths are common additional dating parameters. Special curves are available for non-Caucasian ethnicity or multiple gestation.

Fetal Growth

Serial measurements over time are the best way to judge fetal growth. The sac and embryo grow perceptibly each day; by the second trimester, intervals of 2 or 3 weeks are more reliable. Problems arise when attempting simultaneously to assign age and weight percentile without reliable dating. The abdominal circumference is a better indicator of decreased perfusion or increased glycogen storage than the cranial measures; ratios of abdominal circumference to the head and femur amplify the differences but have poor sensitivity and specificity. Strategies to identify small-for-date fetuses have included risk panels, Doppler ratios, amniotic fluid volume, placental scores, and biometry-based weights; none have had completely satisfactory results, although outcomes appear to have improved.[39] Even accurate estimation of fetal weight is an unrealized basic goal. Critical obstetric and neonatal decisions regarding viability or delivery method rely on ultrasound-derived weights, which vary from true values by more than 10%, and more at the extremes. Clinical algorithms and physician and maternal estimates compare well with ultrasound in estimating birth weight.

Placental Location

Placental location can be confidently established by transvaginal US. Low-lying placentation persists as placenta previa in only 1% to 2% of patients at term (Fig. 9-24). Using color Doppler, fetal vessels can be seen near the cervix, facilitating the diagnosis of funic presentation and vasa previa (Fig. 9-25). US is also helpful in finding placental accretion, the absence of a normal cleavage plane between decidua and placental vessels. Accretion, deeper penetration of the vessels into the myometrium (incretion), and serosal penetration (percretion) were previously diagnosed when failed attempts to deliver the placenta were followed by massive hemorrhage. Placental accretion is more likely in women with placenta previa and a history of cesarean section,[24] after myomectomy or curettage, and with high parity. The frequency of accretion has increased more than 10-fold in the past 20 years to 1 in 2500, echoing rising cesarean rates.[35] Diagnostic US findings of indistinct placental margins, attenuated myometrium, and large turbulent placental vessels have sensitivity and specificity in the range of 85%.[19] Antepartum diagnosis permits planning for anesthesia, transfusion, balloon tamponade, arterial embolization, or a scheduled cesarean-hysterectomy (Fig. 9-26). Magnetic resonance imaging (MRI) can be helpful when there is a posterior placenta, after myomectomy, and when ultrasound findings are ambiguous.[6]

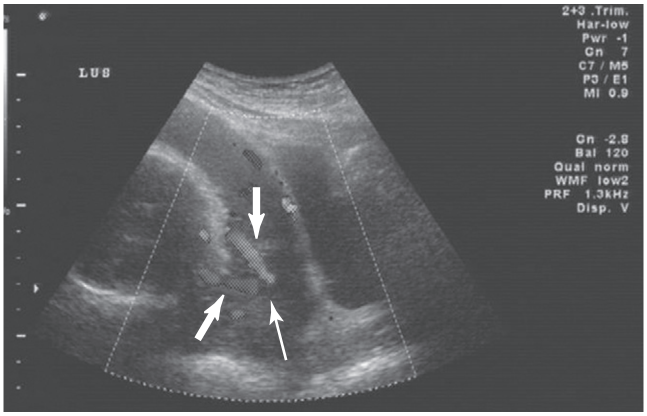

Figure 9–25. Fetal vessels *(thick arrows)* within the membranes overlying the internal os *(arrow)* are termed vasa previa. Rupture of the vessels can rapidly exsanguinate the fetus; artificial membrane rupture and labor are contraindicated. See color insert.

The diagnosis of placental abruption remains a clinical one. US diagnosis is reported to have only 24% sensitivity in the third trimester, although specificity may reach 88%.[26] The role of imaging in this disorder is to exclude placenta previa, an equally common source of severe third-trimester bleeding. Subchorionic hematomas are often noted on transvaginal

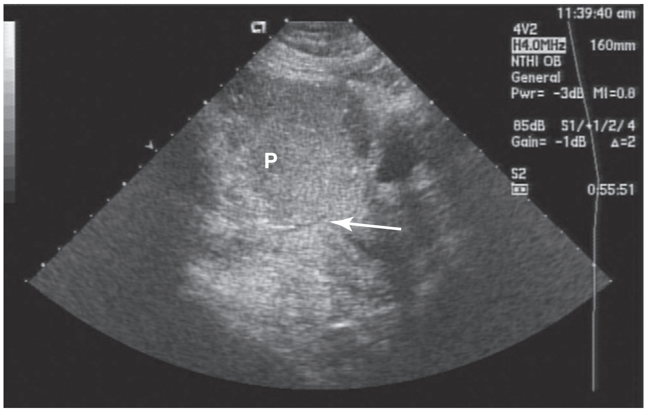

Figure 9–24. Placenta previa: the internal os *(arrow)* is completely covered by the placental tissue (P) in this transabdominal view.

scans early in gestation; symptomaticity, size, and persistence have been linked to poorer outcomes.[37] Later abruptions are more difficult to visualize; acute bleeding is isoechoic with placenta and can be mistaken for placentomegaly. Hypoechoic fluid collections and hyperechoic infarcted areas appear in more chronic presentations. Grading placental appearance to detect disturbed growth or maturation is of limited benefit. Persistent immaturity is linked to hydrops fetalis, although not as often as increased echogenicity and thickening. Precociously mature placentas may presage growth restriction (Fig. 9-27).

Amniotic Fluid Volume

Amniotic fluid volume is initially determined by secretions from the amnion; however, by the 16th week of pregnancy the fetal renal production accounts for the majority (see Chapter 22). Malformations of the esophagus and upper gastrointestinal tract, inhibited fetal swallowing, aneuploidy, intermittent renal obstruction, maternal diabetes, twin-twin transfusion, some cases of dwarfism, and impending fetal hydrops are associated with severe polyhydramnios. Severe growth restriction with polyhydramnios carries a poor prognosis. Polyhydramnios is idiopathic in almost half of cases; the mechanical consequences include prematurity, malposition, abruption, preeclampsia, and puerperal hemorrhage. Abnormal volumes are subjectively apparent to experienced examiners but quantification remains a research issue. Maximum single pocket sizes or summed pool depths across quadrants conveniently serve as proxies for volume in clinical settings (Fig. 9-28). Oligohydramnios may occur after amniorrhexis; fluid may also decrease after fetal renal compensation for placental hypoperfusion, from functional or obstructive urogenital anomalies, and with severe maternal dehydration. The measurement of amniotic fluid may be combined with nonstress testing and assessment of movements, tone, and breathing to provide reassurance of fetal well-being. The mechanisms of amniotic fluid dynamics, the role of fluid assessment in clinical care, and the appropriate therapies for abnormalities remain poorly understood.[42]

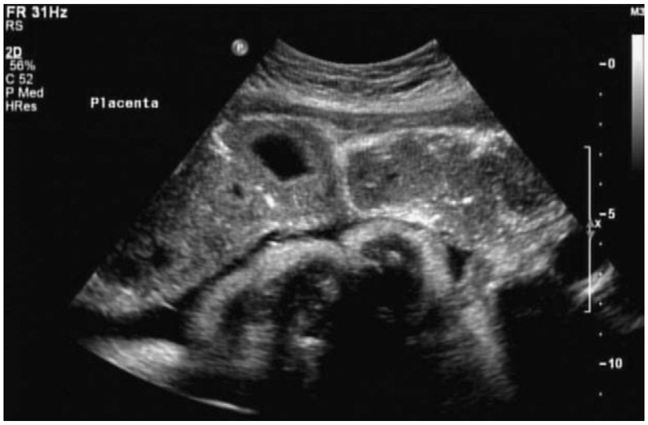

Figure 9–27. Grade III placenta, characterized by echogenic outlines of the cotyledons with hypoechoic centers.

Cervical Length and Pelvic Structures

Cervical length (CL) is often measured as part of antenatal US, using the vaginal approach in borderline or at-risk patients (Fig. 9-29). The length of the closed portion of the endocervical canal seems continuously correlated with duration of gestation; moreover, once values fall below 25 mm, preterm deliveries increase.[20] In patients with known prematurity risks, shorter cervical length is strongly predictive of delivery before 36 weeks; combined with assays for fetal

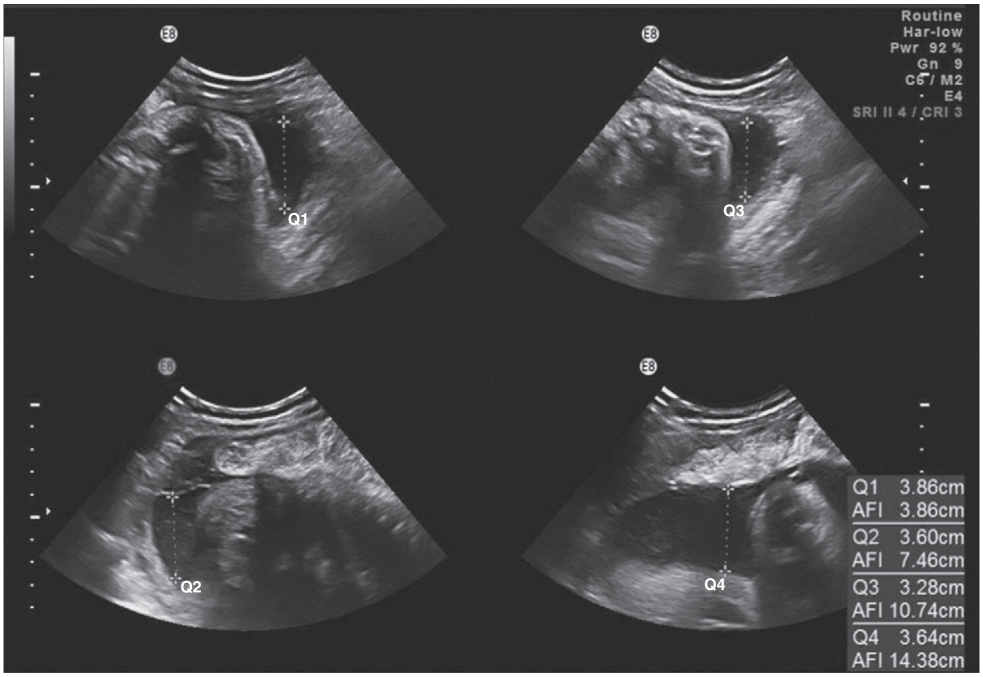

Figure 9–28. Four quadrant vertical pocket assessment of amniotic fluid; other techniques include measurement of the single greatest vertical pocket or identification of a 2 × 2-cm cord-free area.

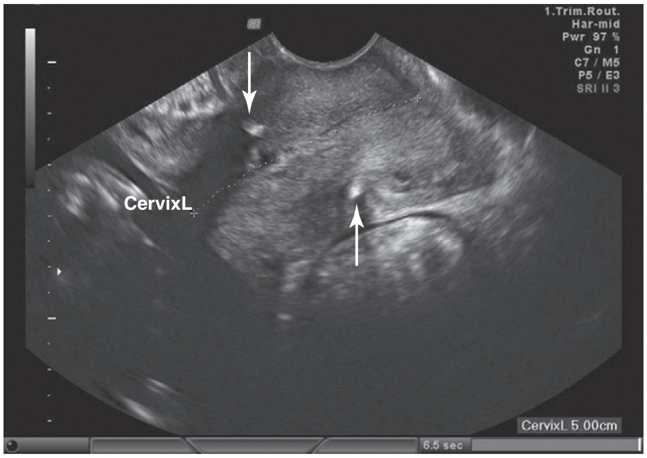

Figure 9–29. Transvaginal study showing cervix *(dotted line)* with MacDonald cerclage *(arrows)* in situ.

fibronectin and other biomarkers, US can be used to find those at highest risk for imminent delivery.[29] Attempts to reduce prematurity using tocolysis have been ineffective; however, delaying birth long enough for steroid enhancement of lung maturity has proven more feasible. First trimester screening by US to detect the need for cervical cerclage is not reliable. Specific candidates may benefit, however, from either preventive and "rescue" procedures on the basis of midtrimester cervical length. Progesterone supplementation by injection or vaginal suppository has increased in recent years; the latter has some supporting evidence for effectiveness when a short cervix is noted by US.[10]

The gravid uterus is conveniently studied by US. Müllerian duplications and septations occur in about 0.5% of the population (Fig. 9-30). Patients with bicornuate uteri may experience irregular bleeding in early pregnancy, alterations in cervical competency, and rarely torsions or cornual ruptures. Poorly vascularized septations are etiologically associated with abruption. Myomas complicate 1% to 2% of pregnancies, with more frequent cesareans and prematurity, abruption, degeneration, and fetal malposition; less common complications include fetal deformation, dystocia, puerperal hemorrhage, and hysterectomy.[30,41] Normal adnexal structures are not palpable after the first trimester; thus ultrasound is currently the first choice for ovarian evaluation during pregnancy, often augmented by MRI and computed tomography (CT). Ovarian torsion is an acute surgical emergency; although rare, it is more likely with ovarian cysts and adnexal masses, favoring first trimester or puerperium onset. Absent Doppler flow, free fluid, and demonstration of twisted vessels or of an edematous, rapidly enlarging ovary aid in expedient recognition and treatment.[17] Corpora lutea, hydrosalpinges, theca lutein, and dermoid cysts are frequent findings, expectantly managed based on reassuring ultrasound, Doppler, and MRI characteristics.[13] Ultrasound is an initial step in the workup of appendicitis during pregnancy; after nondiagnostic studies, spiral CT, MRI, or exploratory surgery may be needed.

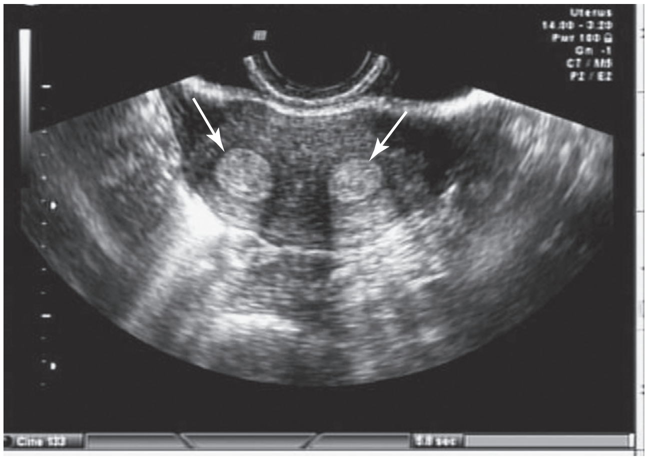

Figure 9–30. Müllerian anomaly: Bicornuate uterus in transverse view with two decidualized cavities *(arrows)* and indented external contours.

In the course of second trimester studies of fetal size, number, placentation, and amniotic fluid, a number of structures are routinely imaged. Basic examinations usually include documentation of fetal cranial integrity; midline brain structures, cavum and thalami, lateral and third ventricles, choroid plexus, cerebellum, and posterior fossa. Increased nuchal thickness is associated with a range of adverse outcomes but is rarely found, yielding a low positive predictive value.[43] Views confirming facial symmetry, intact orbits, lenses, nares, lips, and normal profile are routine in comprehensive studies. Fetal swallowing and respiratory movements may be noted. The spinal column is normally imaged in both the long-axis and coronal views. Some distinct advantages in the visualization of the facial features, small parts, and spine are offered by three-dimensional imaging (Fig. 9-31). Views of the thorax, particularly those of the axis, site, and relative proportions of the cardiac and mediastinal structures with respect to the fetal lung and pulmonary vessels, provide indirect support for the integrity of the diaphragm. The cardiac examination has gradually expanded from documenting axis, laterality, and rate to a requisite symmetric four-chamber view, with routine efforts to ascertain normal outflows, and ductal and aortic arches (Fig. 9-32). Prenatal cardiac studies may include M-mode rhythm, Doppler flow studies, and structural studies capable of approaching in detail and diagnostic accuracy postnatal echocardiology, although subject to some predictable limitations. Abdominal views confirm the closure of the ventral wall, normal situs of the liver and gastric bubble, unremarkable umbilical cord appearance, normal renal and adrenal contours, bowel dimensions and echogenicity, bladder filling, and the presence of the spleen and gallbladder. The accuracy of the assignment of fetal sex increases to greater than 98% halfway through the second trimester (see Figs. 9-12 and 9-70). Small parts, including digits, benefit from three-dimensional and improved conventional resolution.

DOPPLER ULTRASOUND

Initially greeted as a key imaging method, Doppler ultrasound has been hampered by costs, time constraints, safety concerns, and a lack of clear benefit for most patients. Current applications, still more frequent in research and referral

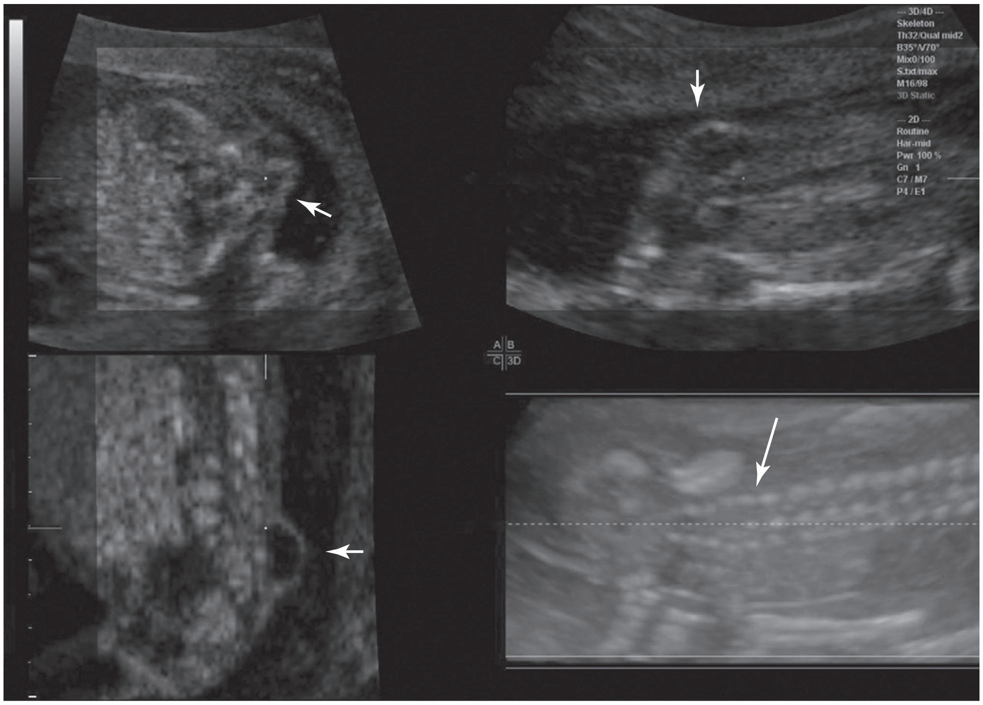

Figure9–31. Three-dimensional rendering of the fetal spine permits localization of the neural tube defect (indicated by *arrows*). Compare with MRI in Figure 9-35. See color insert.

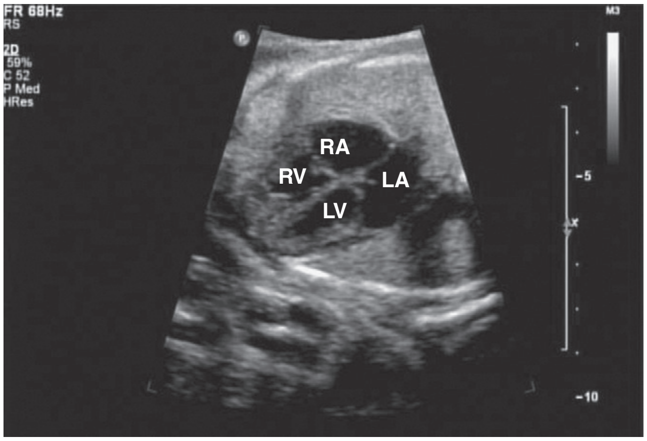

Figure 9–32. Transverse view of the thorax showing a normal four-chamber heart, apex down and to the left of the picture. The right and left atria (RA, LA) and corresponding ventricles (RV, LV) lie in the transverse plane in the fetus.

centers, include measurements of uterine artery bloodflow, umbilical cord, the ductus venosus, and middle cerebral artery, among others. Uterine bloodflow patterns reflect maternal vascular resistance and placental site.[31] Abnormal patterns precede growth restriction and maternal hypertensive complications. Umbilical cord arteries are readily identified by color Doppler as they bifurcate around the bladder (see Fig. 9-5). A two-vessel cord may have associated cardiac and renal anomalies, aneuploidies, or growth restriction. Abnormally high umbilical artery resistance is characteristic of uteroplacental constraints on fetal growth or, less frequently, fetal anomalies. Doppler findings may hint at the etiology of a size/date discrepancy; weight estimation more reliably identifies small-for-gestational age (SGA) fetuses. Persistent absence or reversal of end-diastolic flow, although uncommon, is associated with severe growth restriction and increased perinatal morbidity and loss. Middle cerebral artery resistance and venous patterns are altered later in the course of compromised perfusion; paradoxical ductus venosus or umbilical venous patterns may be premorbid findings. Schemes that combine clinical risk factors, biometry, Doppler findings, and biophysical parameters appear to have improved outcomes for SGA infants.[3]

Doppler measurement of peak systolic velocity in the middle cerebral artery has become incorporated in the management of fetal anemia and isoimmunization (Fig. 9-33). Previously, abnormal maternal antibody levels signaled the need for invasive cord blood sampling or amniocentesis. The former is associated with technical obstacles, fetal losses, and prematurity; the latter was informative only for hemolytic sources of anemia. The peak velocities of the middle cerebral artery are negatively correlated with hemoglobin values, are noninvasive, and are relatively easy to obtain. At a cutoff of 1.5 multiples of the mean (MOM), the sensitivity for moderate to severe anemia approaches 100%, with a false-positive rate from 0% to 28%; reliability drops near term.[33]

Color flow Doppler can distinguish between cystic and vascular lesions, confirm the presence or site of organs, and evaluate central nervous system, cardiac, and pulmonary vascular anatomy. When combined with three-dimensional scanning, color flow can provide a virtual vascular cast, although direct clinical applications are currently limited.

PROCEDURES

Real-time ultrasound is well suited by virtue of safety, economy, and convenience for guiding placement of needles, cannulae, catheters, and other devices used in fetal diagnosis and therapy. The range of procedures includes egg retrieval and

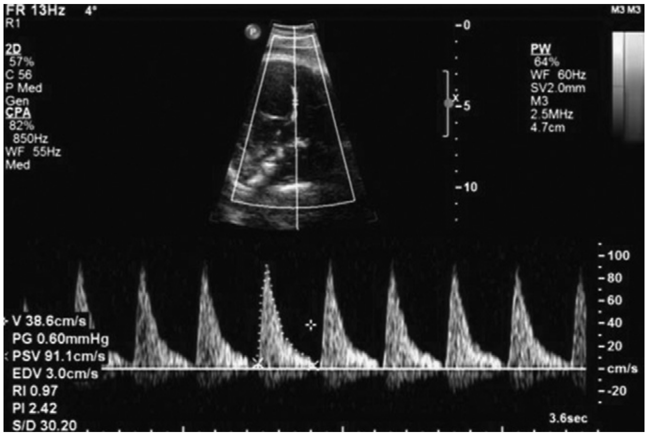

Figure 9–33. Middle cerebral artery (in trapezoid) Doppler flow velocity in a fetus with Rhesus sensitization. The peak systolic velocity (PSV shown in lower portion) increases as fetal anemia progresses. Doppler measurements in the fetus are often expressed as ratios to compensate for inaccuracies introduced by narrow, tortuous vessels. See color insert.

embryo transfers, embryonic and fetal reduction, chorionic sampling, placental and skin biopsies, amniocentesis and amnioreduction, cord blood sampling, intrauterine transfusion, aspiration of fluid from various sites, and in conjunction with fetoscopy and vascular ablation. The effects of interventions can be continuously monitored during and after the procedures. Determination of fetal and umbilical cord positions during delivery, versions, and immediately before transfusions, surgical interventions, and the EXIT (*ex* utero *i*ntrapartum *t*reatment) procedure are also important applications.

FETAL ANOMALIES

(See also Chapter 29.)

Neonatal and parental outcomes may be optimized by advance warning and timely preparations for a range of abnormalities. Unfortunately, more than one third of anomalies detectable after delivery are not recognized prenatally.[27] False-positive rates are usually less than 10%, but discordancy with autopsy findings emphasizes limits inherent in US. Nonetheless, ultrasound is the accepted initial approach for finding fetal malformations (Box 9-1).

BOX 9–1 Indications for Antenatal Ultrasound

- Pregnancy dating
  - Uncertain dates
  - Scheduled delivery
  - Suspected fetal death
  - Late registrant
  - Pregnancy termination
- Fetal size and growth
  - Size/dates discrepancy
  - Suspected polyhydramnios
  - Suspected oligohydramnios
  - Suspected multiple gestation
  - Maternal risk factors for abnormal growth
- Vaginal bleeding
  - Suspected abruption
  - Placenta previa
  - Follow-up for previously identified previa
- Cervical assessment
  - Incompetent cervix
  - Adjunct to cerclage
  - Prematurity risk
- Pelvic pain or pelvic mass
- Suspected hydatidiform mole
- Suspected uterine abnormality
- Fetal localization
  - Suspected ectopic
- Fetal position/weight in labor or after amniorrhexis
  - Adjunct to breech version
  - Adjunct to amniocentesis and other procedures
- Fetal anatomic survey
  - Abnormal serum screening/maternal age
  - Prior history of anomaly
  - Follow-up of detected anomaly
  - Teratogen exposure
  - Known maternal risks for anomalies
  - Isoimmunization/fetal anemia risks

Central Nervous System

FETAL VENTRICULOMEGALY

(See also Chapter 40.)

Strictly speaking, hydrocephalus and ventriculomegaly are not synonymous. Hydrocephalus connotes raised intracranial pressure; this functional observation cannot be made by ultrasound. The lateral ventricles may be enlarged (Fig. 9-34), without altered pressure, because of a developmental abnormality. Enlargement of the atrium and posterior horns of the lateral ventricles (colpocephaly) often occurs in association with agenesis of the corpus callosum or type II Chiari malformation. The lateral ventricles may also be wider as a result of brain destruction from a variety of causes, including ischemia and in utero infection by cytomegalovirus. A single measurement at the level of the atrium of the lateral ventricle is used to define ventriculomegaly; measurements exceeding 10 mm are considered abnormal.[15] The width of the atrium varies little during pregnancy. The normal choroid plexus position depends on gravity; on standard axial views the choroid, attached at the level of the foramen of Monro, rests on the dependent wall of the lateral ventricle. It marks the limit of the lateral ventricle even when the wall itself cannot be seen; a "dangling" choroid plexus establishes the extent and severity of ventricular enlargement (Fig. 9-35).

The clinical outcome with markedly dilated ventricles has been discouraging. Survivors are often mentally and physically impaired. Unfortunately, it has proved impossible to define a group of fetuses with ventriculomegaly who might benefit from in utero shunting. Mild ventriculomegaly, more common in males (atrial size between 10 and 15 mm) has an uncertain prognosis; the majority of infants are normal.

Agenesis of the corpus callosum can be an isolated finding or more commonly associated with other brain anomalies.

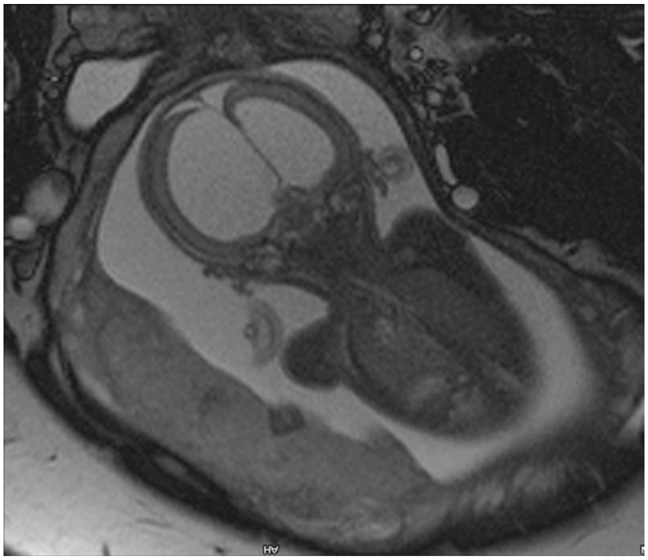

Figure 9–34. Fetal MRI of hydrocephalus at 23 weeks' gestation. Note massive enlargement of both lateral ventricles with thin rim of remaining brain parenchyma.

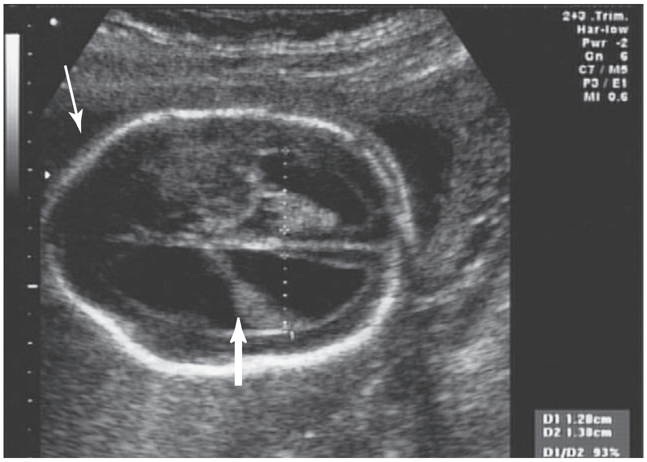

Figure 9–35. "Dangling choroid" *(thick arrow)* with bilaterally dilated lateral ventricles secondary to an open neural tube defect. The latter is signaled by scalloping of the frontal bones, "lemon sign" *(thin arrow)*.

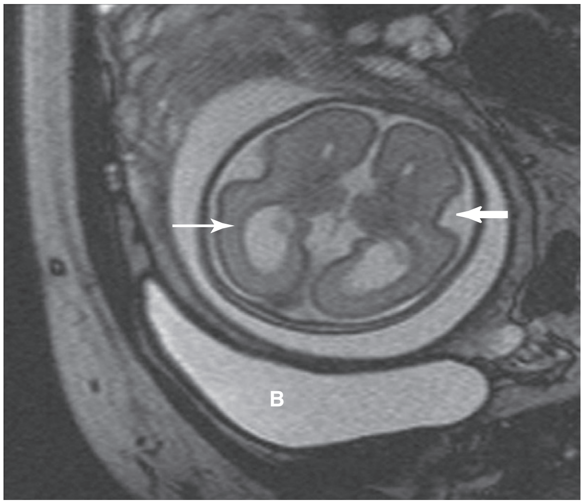

Figure 9–36. MRI at 25 weeks' gestation with agenesis of corpus callosum. Enlarged posterior lateral ventricles-colpocephaly *(thin arrow)*. Rectangular "wide open" Sylvian fissure *(thick arrow)* is normal for this gestational age. Maternal urinary bladder (B).

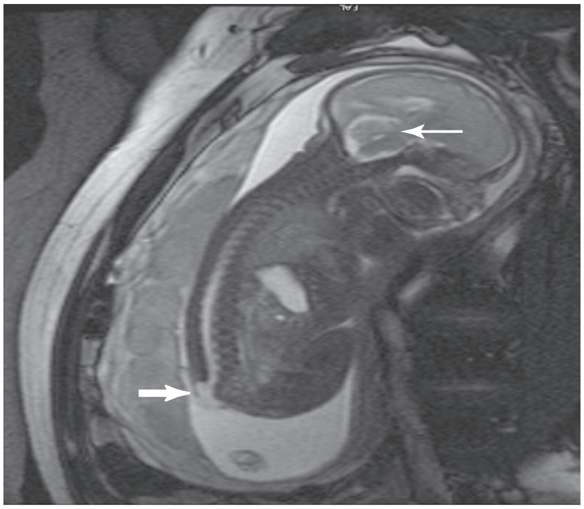

Figure 9–37. MRI of sacral meningomyelocele *(thick arrow)* at 21 weeks' gestation; normal posterior fossa including cerebellum and fourth ventricle *(thin arrow)*.

Ultrasound diagnosis can be challenging before 20 weeks, and MRI examination can be helpful (Fig. 9-36).

MENINGOMYELOCELE AND (TYPE II) CHIARI MALFORMATION

A meningomyelocele (Fig. 9-37) can occur in association with downward displacement of the hindbrain and with other brain anomalies. It may or may not include ventriculomegaly. Often hydrocephalus does not develop in these children until after birth. In cases of an open neural tube defect (Fig. 9-38), the α-fetoprotein level is elevated in both maternal serum and amniotic fluid (see Chapter 8).

A meningomyelocele is demonstrated by ultrasound as splaying or divergence of the posterior ossification centers, which is best appreciated on axial views of the spine. A fluid-filled sac may be seen, and the integrity of the overlying skin can be assessed. The level of the meningomyelocele can also be ascertained, with three-dimensional ultrasound and MRI (see Figs. 9-31 and 9-37) being the most accurate. This information can be helpful for predicting the outcome in affected children.

VENTRICULOMEGALY

The "lemon sign" refers to the altered appearance of the calvaria, similar in shape to a lemon, on an axial scan (see Fig. 9-35).[36] The biconcave frontal bones produce the calvarial distortion. This sign is dependent on gestational age, which is demonstrated between 18 and 24 weeks and is not

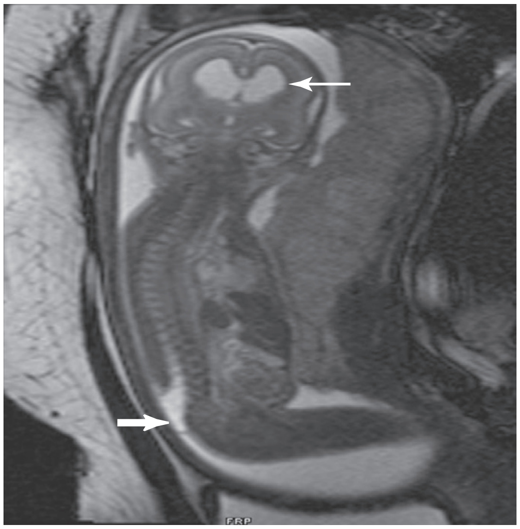

Figure 9–38. Fetal MRI of Chiari II malformation at 21 weeks' gestation. Sacral meningomyelocele *(thick arrow)* and dilated lateral ventricles *(thin arrow)*.

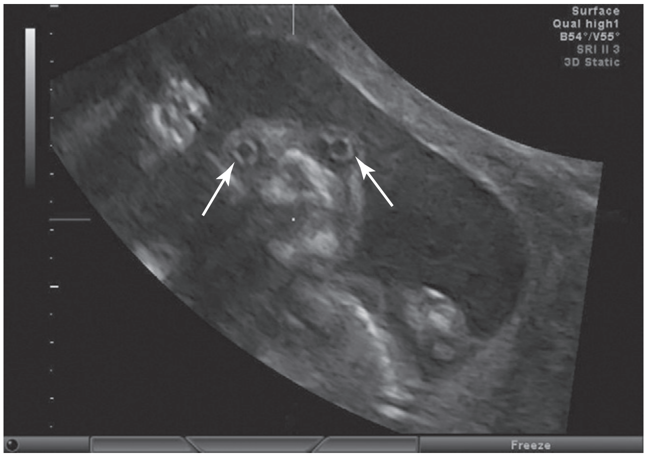

Figure 9–40. Two-dimensional image of anencephaly at 17 weeks' gestation. The cranial vault is absent above the orbits *(arrows)*.

totally specific; it is sometimes found in otherwise normal children. The "banana sign" refers to an abnormal position of the cerebellum, which is curled in a crescent (banana-like) around the brainstem (Fig. 9-39). Obliteration of the cisterna magna and cerebellar distortion are secondary to downward displacement of the hindbrain, which is associated with type II Chiari malformation.

ANENCEPHALY

Anencephaly, which is the absence of the normal brain and calvaria superior to the orbits, can be detected as early as 10 weeks but is recognizable throughout gestation (Fig. 9-40). Associated polyhydramnios (50%) appears late in the second trimester. Maternal serum α-fetoprotein is elevated in most cases. Approximately 50% have associated anomalies, such as meningomyelocele, cleft palate, and clubfoot. Occasionally the typical appearance is altered by the presence of echogenic material superior to the orbits, identified pathologically as angiomatous stroma ("area cerebrovasculosa"). Anencephaly is considered incompatible with meaningful postnatal survival.

ENCEPHALOCELE

(See also Chapter 40.)

The protrusion of brain tissue within a meningeal sac is usually a straightforward ultrasound diagnosis. Most encephaloceles in the Western world are occipital and midline, and a distinction should be made between them and soft tissue edema or cystic hygroma of the neck. The identification of the bony calvarial defect allows a specific diagnosis (Fig. 9-41). Encephaloceles may occur in isolation or be associated with amniotic band syndrome (when off midline) and genetic syndromes such as Meckel-Gruber.

DANDY-WALKER CYST

Dandy-Walker malformation is a fluid-filled cyst of the posterior fossa with or without enlargement of the lateral ventricles (Fig. 9-42). Enlargement of the posterior fossa is always present

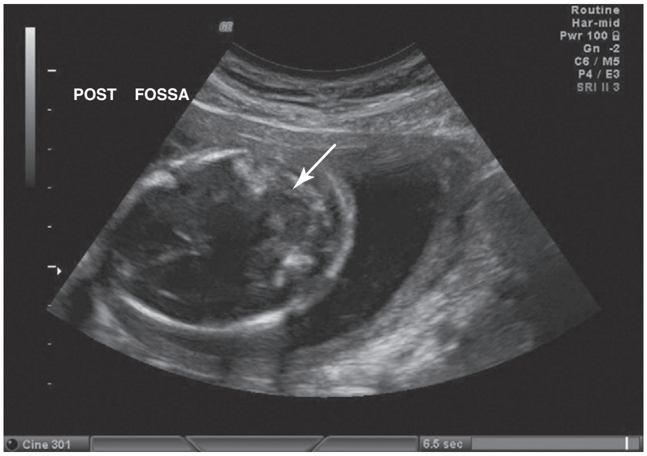

Figure 9–39. Open neural tube defects may be associated with an obliterated posterior fossa "banana sign" *(arrow)* in 60% of cases.

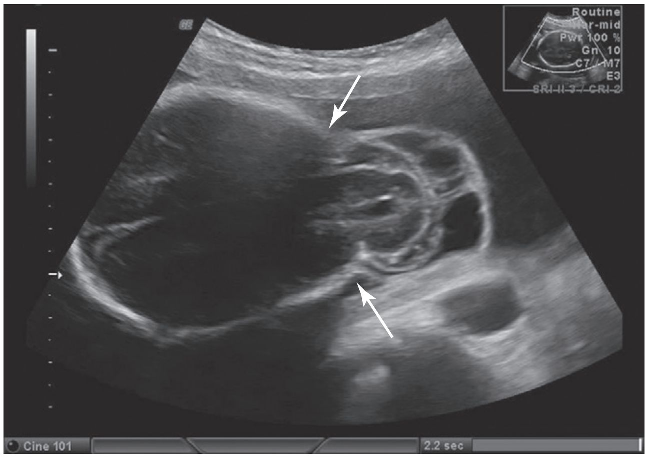

Figure 9–41. Large occipital encephalocele with herniation of neural tissue through the defect *(arrows)*.

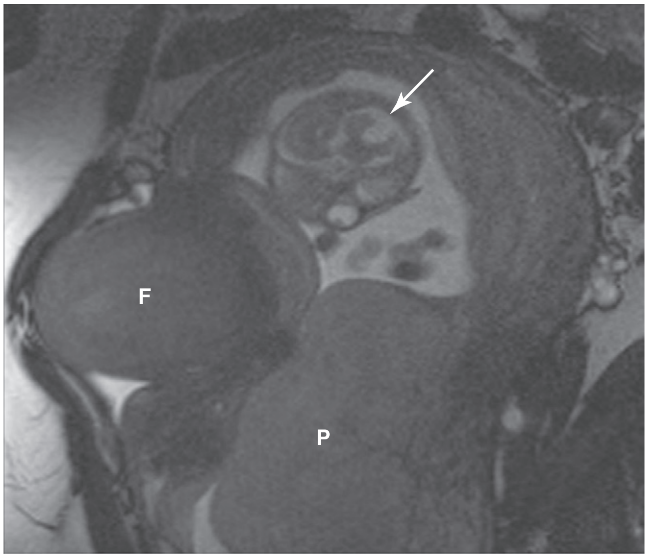

Figure 9–42. Fetal MRI of Dandy-Walker cyst *(arrow)* at 20 weeks' gestation. Note the posterior placenta (P) and anterior fibroid (F).

with uplifting of the tentorium. The cerebellar hemispheres are rudimentary, separated by the posterior fossa cyst. Agenesis should not be diagnosed before 18 weeks because the development of the cerebellar vermis may not be complete until that time.

The Dandy-Walker variant, associated with an increased incidence of chromosomal abnormalities, consists of direct communication between the fourth ventricle and cisterna magna without posterior fossa enlargement. The inferior cerebellar vermis is only mildly hypoplastic. These ultrasound findings can be subtle and confirmation from MRI helpful (Fig. 9-43).

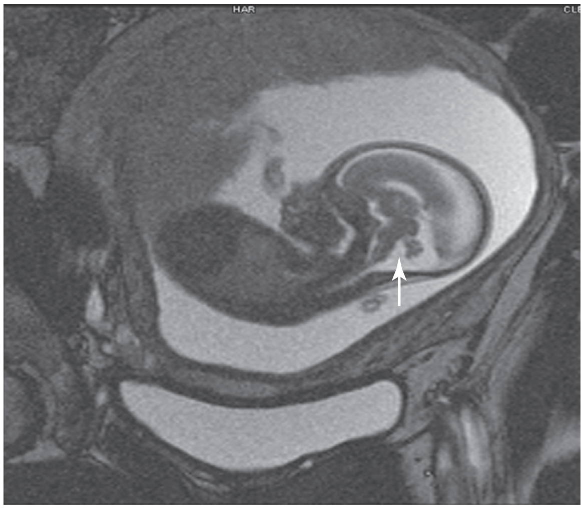

Figure 9–43. Fetal MRI of Dandy-Walker variant at 21 weeks' gestation. Remaining cerebellum is uplifted with wide inferior communication of fourth ventricle *(arrow)*.

CHOROID PLEXUS CYST

Cysts in the choroid plexus are identified in 1% to 2% of normal pregnancies in the second trimester and usually resolve by the early third trimester (see Fig. 9-17). Choroid cysts have been associated with aneuploidies, including trisomies 18 and 21, although rarely as isolated findings. Number, size, and persistence of cysts lend no additional clinical significance to the finding.

Spine

Spinal anomalies demonstrable by ultrasound include congenital vertebral anomalies (Fig. 9-44). Sacrococcygeal teratoma is a large mass arising posteriorly from the rump of the fetus. The posterior elements of the lumbosacral spine are intact. This tumor is often associated with polyhydramnios and prematurity and more rarely with hydrops. The mass may be cystic or solid, extend into the fetal pelvis (Fig. 9-45) and abdomen, and rarely undergo malignant degeneration.

Head and Neck

After 14 weeks, the visualization of the nose, orbits, forehead, lips, and ears is feasible. Orbits are clearly seen axially; the ocular diameters, interocular distance (defining hypertelorism and hypotelorism), and binocular distance are measured. The profile reveals the forehead, nose, and jaw sagittally (contrast Fig. 9-1 with Fig. 9-46). The coronal view, the best for facial structures, includes the orbits (and lenses), eyelids, nose, and lips. The coronal view demonstrates facial clefting abnormalities, including the cleft lip and cleft palate, which may be central or lateral. Sagittal views should include the nasal bone; nasal bone hypoplasia or absence is used by some as a marker for Down syndrome. The complex anatomy of the fetal face is shown exquisitely by three-dimensional sonography (see Fig. 9-8; Fig. 9-47).[28]

Cystic hygroma (lymphatic malformation) is a septate, cystic mass arising in the neck and occiput; it may extend to the remainder of the trunk (Fig. 9-48). Posterior septation of the nuchal ligament distinguishes this lesion from neural

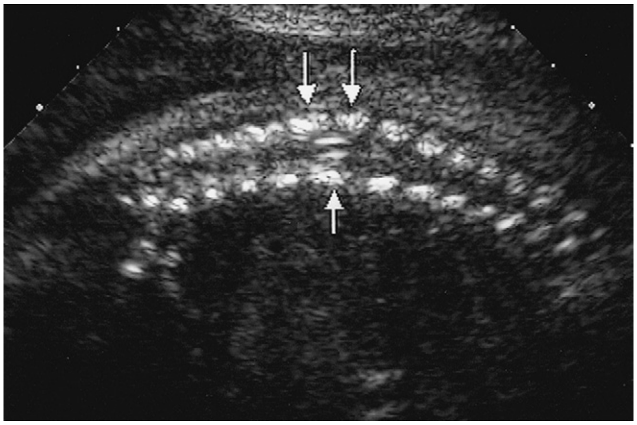

Figure 9–44. Coronal view through the fetal spine showing a hemivertebra. The spinal ossification center *(upper left arrow)* has no mate.

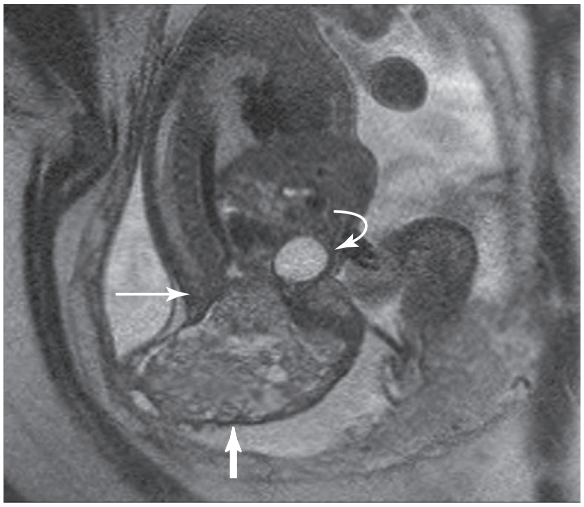

Figure 9–45. Fetal MRI of sacrococcygeal teratoma at 27 weeks' gestation. Tumor *(thick arrow)* extends into fetal pelvis between spine *(thin arrow)* and urinary bladder *(curved arrow)*.

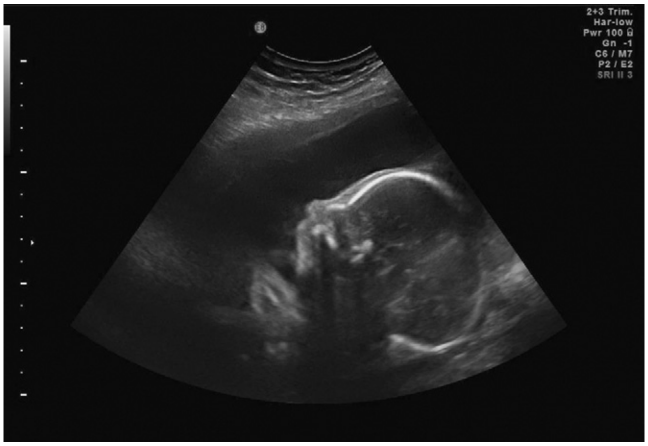

Figure 9–46. Fetal retrognathia (recessed chin) is a feature of a variety of syndromes and aneuploidies, as noted in this fetus with trisomy 18.

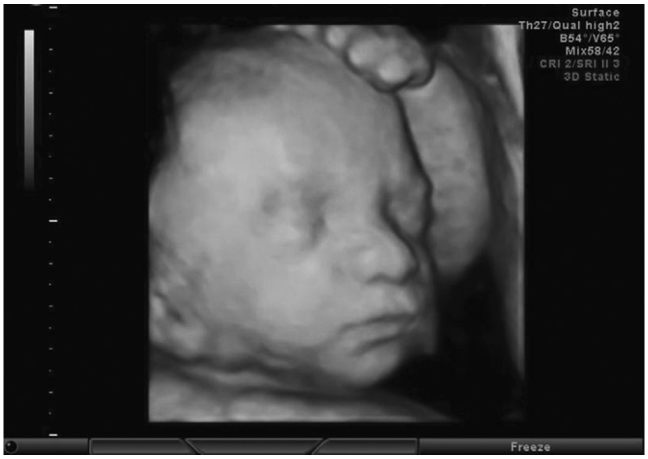

Figure 9–47. Unremarkable fetal face shown three dimensionally at 34 weeks' gestation. Views are optimized by adequate fluid interface, lack of fetal movement, limited maternal adipose and scarring tissues, and posterior placentation. See color insert.

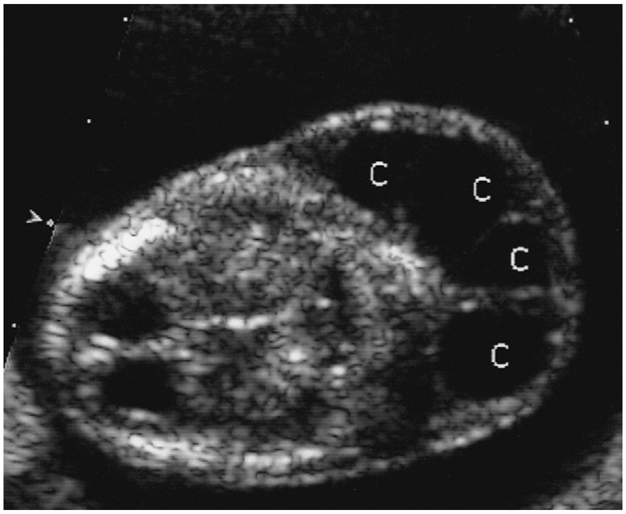

Figure 9–48. Transverse image through the head showing a posteriorly located cystic hygroma with multiple septate cysts (C).

tube defects. Associated aneuploidies, including monosomy X, are common. Less frequent neck masses include anterior goiter, teratoma, and hemangioma.

Increased nuchal translucency (subcutaneous sonolucent area) (see Fig. 9-11) and nuchal thickness (see Fig. 9-16) are associated with aneuploidies, including trisomies 21 and 18, cardiac malformations, a wide range of other anomalies, maternal diabetes, and fetal loss. With a normal karyotype and reassuring midtrimester cardiac and anatomic surveys, the outcome is generally good.[11] The cause of the transient fluid accumulation in the neck is unknown; the appearance at birth is usually normal.

Heart

(See also Chapter 45.)

Most fetal echocardiograms are obtained at 18 to 20 weeks of gestation; however, the fetal heart may be evaluated as early as 12 weeks with transvaginal ultrasound. Optimal timing is a compromise between offering a diagnosis as early as possible and adequately visualizing complex anatomy, recognizing that some lesions develop late in pregnancy. A four-chamber view of the fetal heart should be part of all obstetric ultrasound examinations (see Fig. 9-32). Abnormal four-chamber views will detect approximately 50% of all cases of congenital heart disease in a nonselected population. Fetal arrhythmias and abnormal situs may also be diagnosed (Fig. 9-49).

An attempt should be made on each study to obtain aortic arch and outflow views, linking the aorta and neck vessels with the left ventricle and the bifurcating pulmonary artery with the right ventricle; these views allow identification of transposition of the great vessels, tetralogy of Fallot, truncus arteriosus, and some aortic abnormalities.[16] Sensitivity for complex cardiac lesions exceeds that for isolated septal

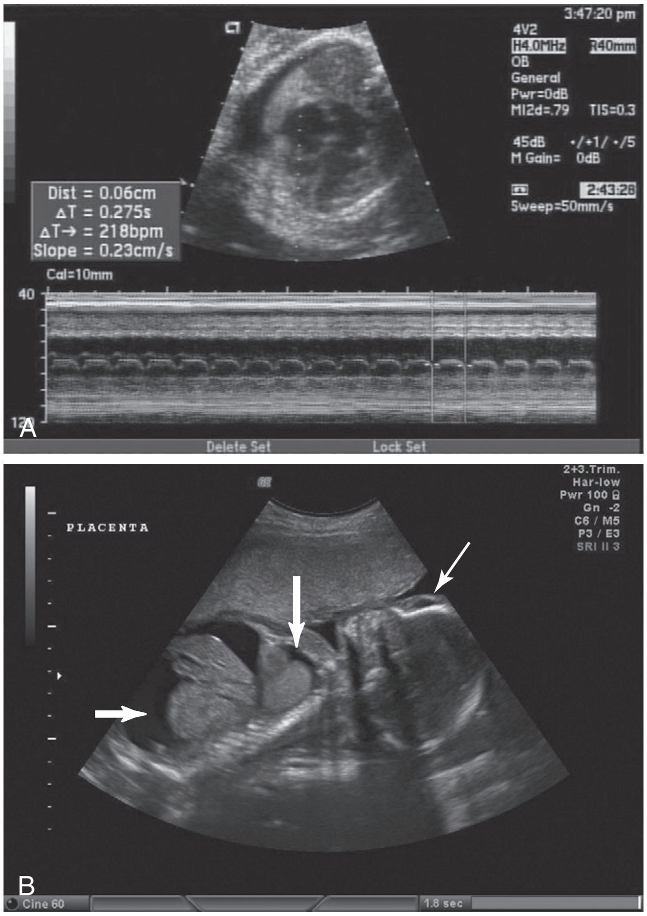

Figure 9–49. Fetal arrhythmia demonstrated by M-mode (**A**), consistent with paroxysmal atrial tachycardia at 218 beats per minute. Sustained rates greater than 200 beats per minute may be associated with fetal hydrops (**B**). The fetus has ascites *(short arrow)*, pleural effusion *(long arrow)*, and skin edema *(thin arrow)*.

defects; however, the correct diagnosis is highly dependent on operator experience.

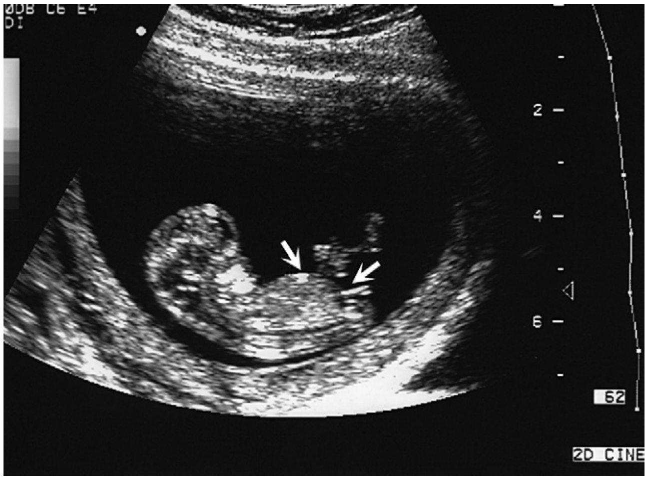

Figure 9–50. A 10-week fetus within its gestational sac. Physiologic midgut herniation occurs from week 8 to week 11.

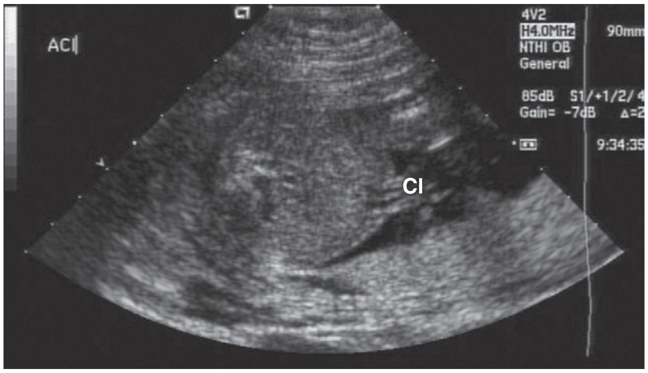

Figure 9–51. Cross section of the abdomen at the level of the umbilical vessels, demonstrating heterogeneous-appearing, nondistended, fluid-filled loops of normal small bowel. The abdominal walls are clearly intact adjacent to the cord insertion (CI).

Gastrointestinal Tract

(See also Chapter 47.)

NORMAL BOWEL APPEARANCE

Physiologic bowel migration into the proximal umbilical cord occurs from 7 to 10 weeks of gestation and may be visible on first-trimester scans (Fig. 9-50) up to 11.5 weeks. The normal liver remains intra-abdominal; migration thus should never be mistaken for ventral abdominal wall defects.[12] The normal fetal stomach is seen transvaginally by 9 to 10 weeks of gestation as an echo-free structure in the upper left abdomen that changes in size as it empties and fills. Fetal small bowel usually is not distinguished early in gestation but appears as fluid-filled loops in the central abdomen by the late second trimester (Fig. 9-51). The large bowel is clearly identified by the third trimester as a hypoechoic tubular structure at the abdominal periphery. Meconium in the large bowel is a normal third trimester finding. Meconium in the second trimester may have increased echogenicity that resolves over time. Hyperechogenic bowel, as bright as adjacent osseous structures, is a nonspecifice abnormal finding linked to poor fetal outcomes. Echogenic bowel has been associated with trisomy 21, cystic fibrosis, bowel atresia, congenital infections (e.g., cytomegalovirus), intrauterine growth restriction, chronic abruption, and poor outcome.

Obstruction of the gastrointestinal tract can be diagnosed by ultrasound. Blockage of the proximal alimentary canal interferes with amniotic fluid turnover, which involves swallowing and absorption by the fetus. In proximal bowel obstruction, polyhydramnios is an invariable finding (see Chapter 22).

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

A nonvisualized fetal stomach combined with polyhydramnios should alert the examiner to the possibility of esophageal atresia. Unfortunately, these two signs are identified in only 40% of the cases. Nonvisualization of the stomach is not specific for esophageal atresia; a proximal esophageal pouch is almost never visualized. Polyhydramnios, which is seen in two thirds of the cases, may not develop until the third trimester. The VACTERL complex consists of *v*ertebral, *a*nal, *c*ardiovascular, *t*racheal, *e*sophageal, *r*enal, and *l*imb malformations; these systems should be scrutinized in the fetus when a tracheoesophageal fistula from poor gastric filling is suspected. The stomach may not fill when there is little to swallow, as in oligohydramnios, or when there are abnormalities of the neural or musculoskeletal system (e.g., Pena-Shokeir syndrome) that interfere with swallowing.

SMALL BOWEL OBSTRUCTION

In duodenal atresia, a distended stomach and proximal duodenum produce a “double-bubble” sign akin to the neonatal x-ray appearance (see Fig. 9-14). The strong (25%) association with Down syndrome may warrant genetic amniocentesis when duodenal atresia is suspected. Other etiologies include annular pancreas, duodenal web, malrotation, and severe duodenal stenosis. Ileal and jejunal atresia usually cause multiple distended bowel loops, often exhibiting peristalsis (Fig. 9-52). More distal bowel obstruction, seen in meconium ileus, Hirschsprung disease, and anal atresia, may not produce noticeably dilated loops of bowel until the third trimester. Meconium peritonitis, a sterile but morbid chemical response to intrauterine bowel perforation, is characterized by echogenic peritoneal calcifications and free intraperitoneal fluid (Fig. 9-53).

ANTERIOR ABDOMINAL WALL DEFECTS

With an approximate incidence of omphalocele of 1 in 5000 and of gastroschisis of 1 in 10,000 live births, abdominal wall defects are among the more common neonatal abnormalities. A midline defect involving the base of the umbilical cord is characteristic of omphalocele (Fig. 9-54). A sac surrounds the herniated viscera and may also include the liver (Figs. 9-55 and 9-56). Omphaloceles are often associated with other anomalies (Beckwith-Wiedemann syndrome, pentalogy of Cantrell) and aneuploidies (trisomies 13 and 18). In gastroschisis, herniated bowel loops float in the amniotic cavity without a covering membrane (Fig. 9-57). The defect is usually to the right of the umbilical cord insertion; associated fetal abnormalities are rare.

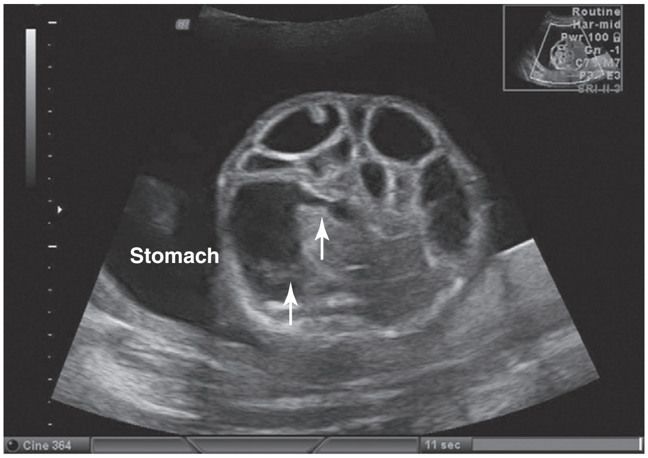

Figure 9–52. Massive dilation of bowel loops secondary to early in utero volvulus with obstruction. The stomach and duodenal bulb are marked with *arrows*. Polyhydramnios is present.

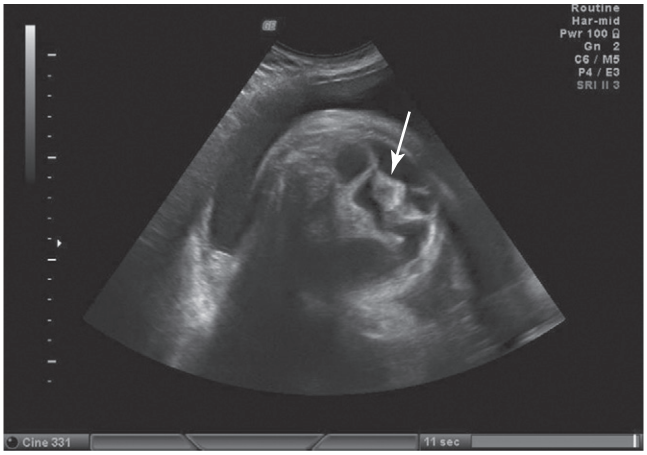

Figure 9–53. Dilation of small bowel loops associated with ileal obstruction and perforation. The echogenic material *(arrow)* is a meconium pseudocyst.

DIAPHRAGMATIC HERNIA AND THORACIC LESIONS

The diagnosis of congenital diaphragmatic hernia (Fig. 9-58) is made when the abdominal organs (usually the stomach and bowel) are seen in the thorax. Fluid-filled loops of bowel may show peristalsis in the thoracic cavity. Left cardiac hypoplasia, polyhydramnios, paradoxical breathing, and other anomalies are often associated (see Chapters 11, 44, and 47).

Diaphragmatic hernia has a mass effect, with a mediastinal shift and lung compression (Fig. 9-59). Unfortunately, the extent of pulmonary hypoplasia, measured at the level of the four-chamber heart, cannot by itself predict postnatal outcome. Among the best current ultrasound predictors are measurements of the lung-to-head ratio and calculated three-dimensional lung volumes. MRI can give precise volumetric measurement of the lungs that can be a helpful adjunct. The presence of liver herniation into the chest (Fig. 9-60) is slightly less ominous for right-sided defects than for those on the left. Cystic adenomatoid malformation (Fig. 9-61) may have a similar imaging appearance but lacks peristalsis and displacement of abdominal structures. Solid forms may be difficult to distinguish from sequestrations; the latter usually display feeding vessels (Fig. 9-62). Spontaneous regression during pregnancy may occur in both sequestrations and cystic adenomatoid lesions.

Gallbladder and Bile Ducts

(See also Chapter 48.)

A choledochal cyst is a localized dilation of the biliary system, often involving the common bile duct. It is seen as a fluid-filled cyst in the upper right abdominal quadrant, separate from the

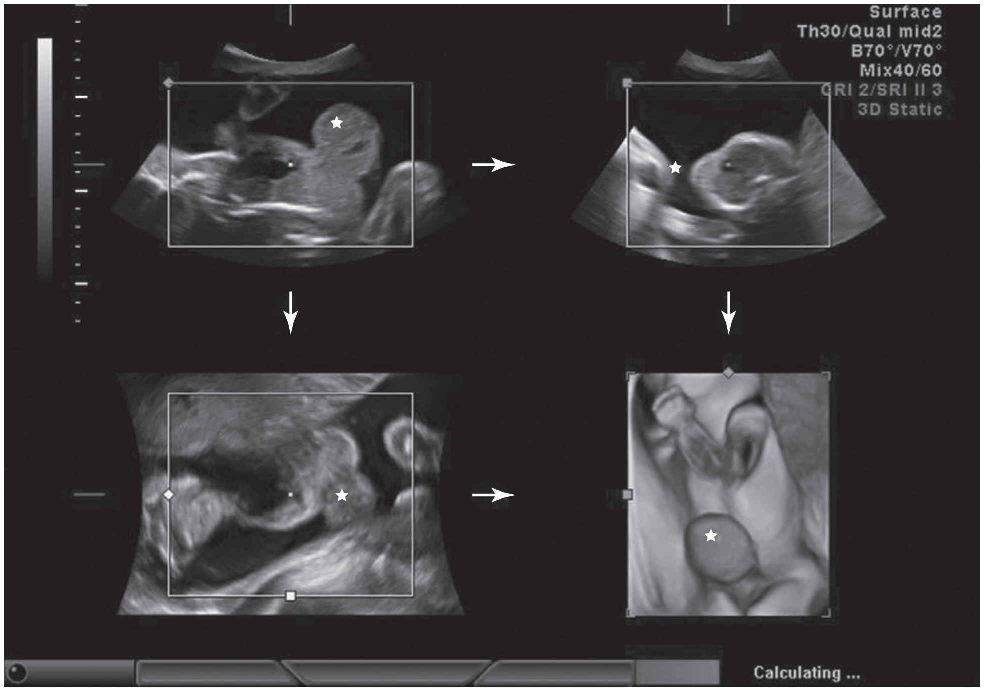

Figure 9–54. Three-dimensional views of an omphalocele *(star)* at 18 weeks' gestation. Upper left: sagittal two-dimensional image; upper right: transverse trunk just above the defect; lower left: coronal image; lower right: three-dimensional view. Contents are best identified on the two-dimensional proportionate size on the rendered image. The small dot is sited within the gastric bubble. See color insert.

gallbladder. Echogenic material (suspected gallstones) is occasionally noted in the gallbladder lumen on third-trimester scans (Fig. 9-63). Follow-up studies in neonates generally confirm resolution; children are usually asymptomatic.

Genitourinary Tract

(See also Chapter 47.)

The kidneys are readily visible by 12 to 14 weeks' gestation; they are located lateral to the fetal spine (Fig. 9-64). Normal kidney size can be plotted against gestational age; by the end

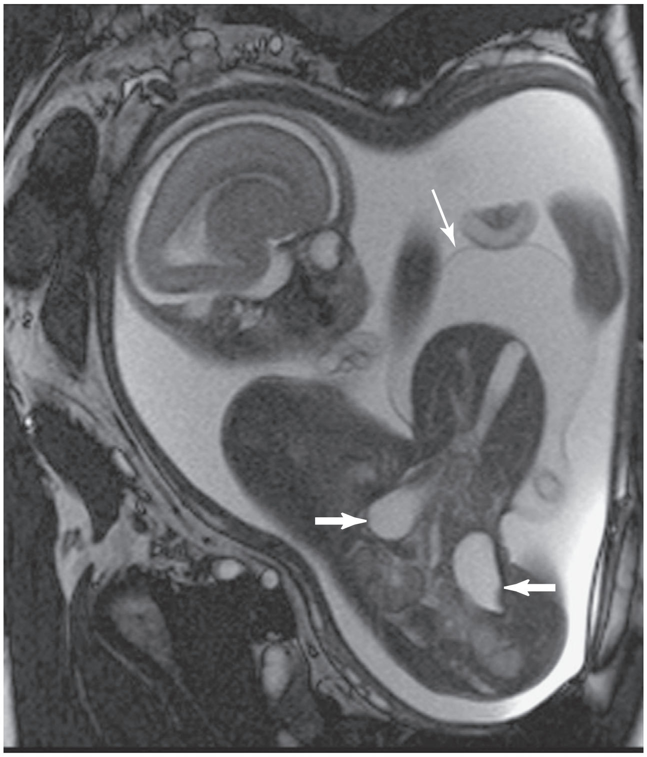

Figure 9–56. Fetal MRI of omphalocele at 24 weeks' gestation. Note membrane *(thin arrow)* covering the omphalocele that includes the liver. Fetal stomach and bladder are shown by *thick arrows*. Note normal smooth brain surface at 24 weeks without gyri or sulci.

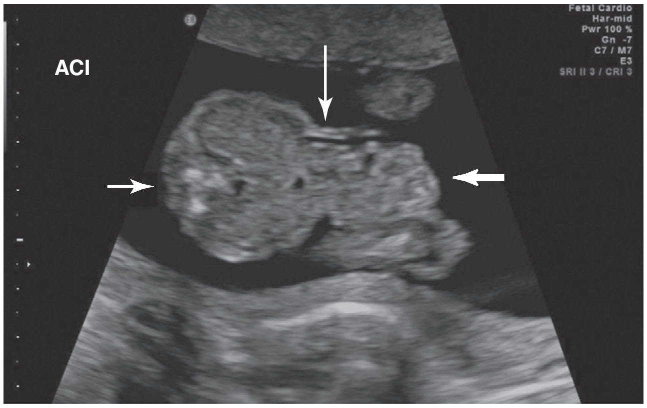

Figure 9–57. Gastroschisis. Transverse abdominal image of the spine (left, *short arrow*) demonstrates free bowel loops *(thick arrow)* to the right of the umbilical cord insertion *(long arrow)*. This lesion is more common in younger gravidas and is usually isolated.

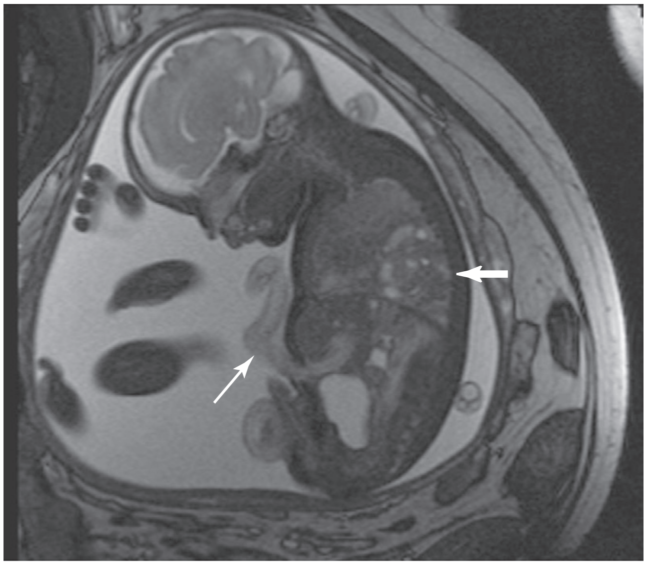

Figure 9–58. MRI of posterior Bochdalek diaphragmatic hernia at 28 weeks' gestation *(thick arrow)*. Also note the umbilical vein *(thin arrow)* entering the fetal liver above the urinary bladder to become the ductus venosus.

of the third trimester, fat deposition creates an echogenic border that enhances demonstration of renal structures. The bladder is visible as early as 11 weeks of gestation, outlined laterally by the umbilical arteries (Fig. 9-65). Normal fetal ureters are never visible by ultrasound. Fetal adrenal glands are easily identified later in pregnancy because of the relatively large cortex.

Lethal renal malfunctions such as bilateral multicystic kidneys or bilateral renal agenesis result in the absence of fetal urine production; oligohydramnios may not become apparent until 18 to 20 weeks of gestation. Amniotic fluid after 16 weeks is almost entirely fetal urine. Infants born after prolonged oligohydramnios have a characteristic facial appearance, limb deformities, and pulmonary hypoplasia, termed *Potter syndrome* (or sequence). Finding oligohydramnios on ultrasound should direct attention to the fetal urinary tract. If the bladder is not seen at first, the patient should be rescanned at 30-minute intervals. Unfortunately, a lack of surrounding amniotic fluid obscures fetal anatomy. Anhydramnios, a persistently empty bladder, and an inability to identify fetal kidneys or renal arteries is strongly suggestive of bilateral renal agenesis. Fetal adrenal glands lose their normal angulation in renal agenesis and may be mistaken for the kidneys. Fetal MRI can be ideal in establishing this lethal diagnosis. Care must be exercised when suspecting unilateral renal agenesis to exclude renal ectopy (pelvic kidney); color

Doppler may reveal the aberrant course of the renal artery (see Fig. 9-4).

Mild dilation of the fetal renal pelvis is common; it is a normal feature that should not be misinterpreted as hydronephrosis. Pyelectasis has been reported to be a "weak" marker for Down syndrome. Identifying a single measurement to predict postnatal obstructive uropathy proved elusive. Pathologic dilation of the upper urinary tract was previously diagnosed when the renal pelvis measured 10 mm or more in the anteroposterior dimension. This measurement failed to identify hydronephrosis before the third trimester; cutoffs of 4 to 7 mm are now used in second and third trimesters, respectively. Obstruction of the urinary tract produces a variable

sonographic appearance, depending mainly on timing of onset. Renal dysplasia, sometimes with cyst formation, is the consequence of early obstruction; obstruction occurring later in gestation is more likely to result in dilation of the collecting system (Fig. 9-66).

Hydronephrosis may be unilateral, resulting from obstruction of the ureteropelvic junction, or bilateral, resulting from lower urinary tract obstruction by posterior urethral valves or urethral agenesis. A distended, thick-walled bladder may be seen in males with posterior valves. Hydroureters are usually present; urinary ascites may occur. "Keyhole" dilation of the posterior urethra helps distinguish this lesion from prune-belly syndrome (Fig. 9-67).

Multicystic renal dysplasia appears as several noncommunicating cysts varying in size, lacking organization, and changing over time. Severe hydronephrosis, in contrast, is an orderly arrangement of the enlarged renal pelvis surrounded by smaller calyces. Bilateral renal anomalies (including bilateral multicystic renal dysplasia) are common (40%) in the fetus (Fig. 9-68).

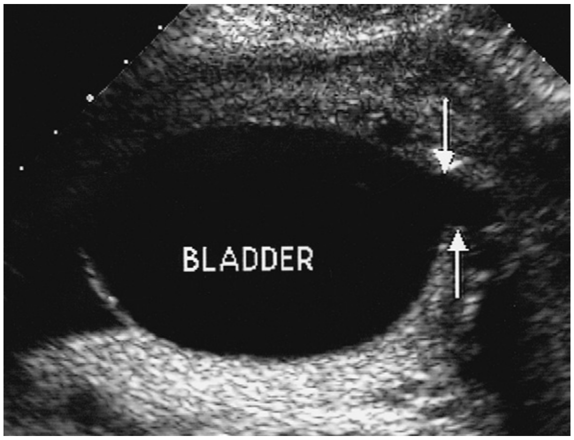

Figure 9–67. Posterior urethral valve. Coronal scan of the fetal pelvis shows an enlarged bladder and dilated posterior urethra. *Arrows* are proximal to the posterior urethral valves. Note the oligohydramnios.

Dilated ureters may be seen in ureterovesical junction obstruction (primary megaureter). Dilated ureters have also been attributed to reflux. Autosomal recessive polycystic kidney disease causes bilaterally enlarged, echogenic kidneys, which retain their reniform shape (Fig. 9-69). Many other renal anomalies have been identified prenatally, including duplicated collecting systems and bladder exstrophy; in the latter condition, persistent nonvisualization of the bladder coincides with normal amniotic fluid and unremarkable kidneys.

Distinguishing a male from a female fetus is reliably accomplished after 16 weeks' gestation (Fig. 9-70) by external genital examination. Ovarian cysts, fluid-filled or septate with fluid levels, are seen in utero; these cysts are often abdominal, resembling gastrointestinal and other abnormal cysts. Hydrometrocolpos is another fluid-filled pelvic structure in females.

Musculoskeletal System

Examination of all four extremities and femur measurements are routine parts of prenatal studies. Standardized tables exist for all the long bones, the feet, and other skeletal components. Shortening of the extremities beyond 3 standard deviations for age is very suspicious for skeletal dysplasia. Because measurements in normal populations are distributed below the 5th percentile, it is reassuring that most skeletal dysplasias show dramatic reductions; an abnormal femur-to-foot ratio also provides diagnostic support. The biparietal diameter continues to reflect gestational age unless the skull is involved in the dysplastic syndrome.

Careful measurement of all bones in the peripheral skeleton is required in suspected cases, first to define the category of dysplasia and then, if possible, to make a diagnosis (see Chapters 29 and 54). Overall limb reduction is termed *micromelia*; *rhizomelia* refers to proximal (femurs and humeri), mesomelia to more distal (forearms and lower legs), and *acromelia* to the most distal (feet and hands) dysplasias. Fractures and curvatures, altered bone density, the appearance of the spine, skull, and ribs, and extraskeletal anomalies may be keys to a specific diagnosis. Polyhydramnios may also be present.

Pulmonary hypoplasia is a frequent cause of death in fetuses with severe skeletal dysplasia. Lung volume can be

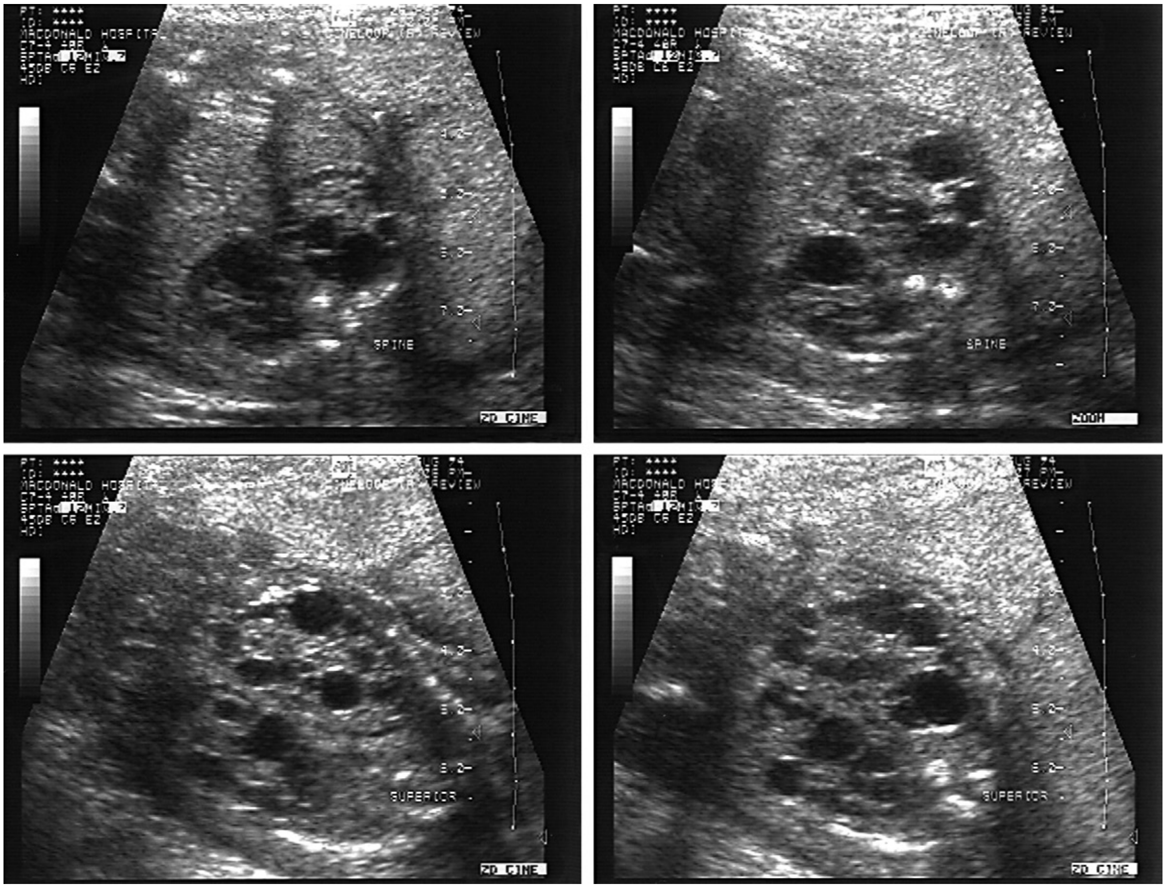

Figure 9–68. Multiple views of bilateral multicystic dysplastic kidneys. This diagnosis is considered incompatible with postnatal survival and is always associated with severe oligohydramnios in the second half of gestation. Note lack of fluid interface.

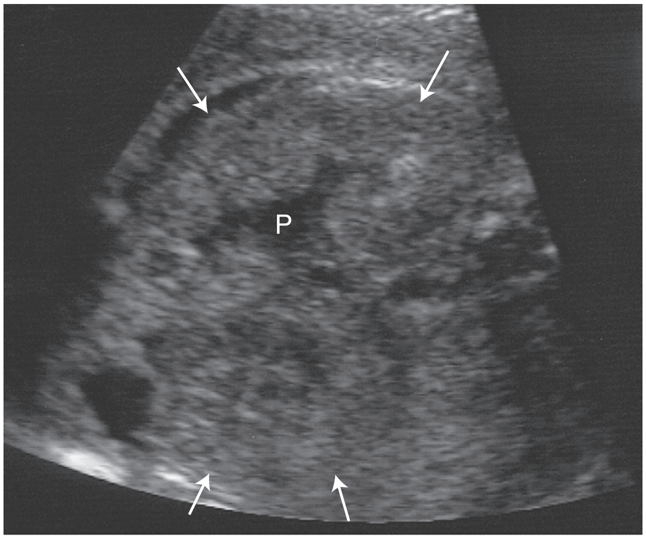

Figure 9–69. Congenital polycystic kidney disease. Transverse abdominal scan shows echogenic, enlarged kidneys filling the fetal abdomen *(arrows)*. The renal pelvis (P) is seen in the superior kidney. Oligohydramnios is present.

assessed by MRI or by three-dimensional imaging, but femur/abdominal circumference of less than 0.16 appears to function as a convenient proxy for more tedious estimators for lethality.[40] Thanatophoric dysplasia is a uniformly lethal skeletal dysplasia that can often be recognized in utero. Features are severe micromelia, curved femurs, and pulmonary hypoplasia (Fig. 9-71). One form of thanatophoric dysplasia includes a cloverleaf skull deformity. Achondrogenesis is also lethal, signaled by severe micromelia and a lack of vertebral ossification.

Lethal type II osteogenesis imperfecta produces short, fractured bones, often bent or curved (Fig. 9-72). Bone density is decreased, best appreciated in the calvaria. The lethal form of hypophosphatasia may have a similar ultrasound appearance of severe demineralization.

Heterozygous achondroplasia is the most common nonlethal skeletal dysplasia. Shortening of the femur characterizes this autosomal dominant, rhizomelic disorder, but may not be noticeable until the third trimester, limiting prenatal diagnosis to known carriers.

Other abnormalities of the musculoskeletal system include the malformation or absence (dysostosis) of various parts of the skeleton, for example, limb reduction anomalies

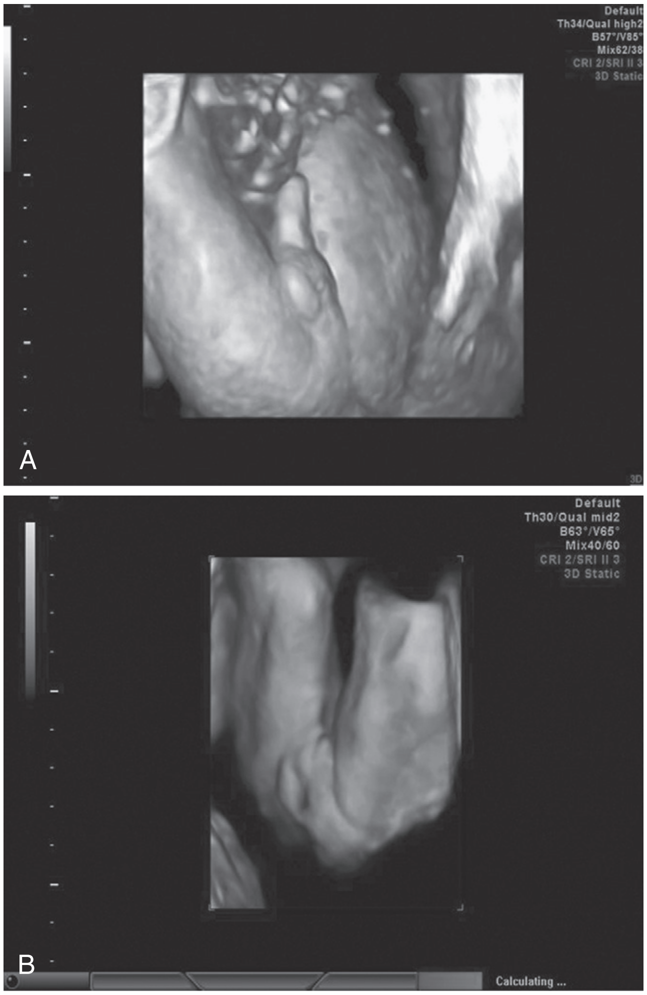

Figure 9–70. The male fetus (A) can reliably be distinguished from the female fetus (B) by ultrasound after the first trimester. See color insert.

as in radial clubhand or hemimelia (Figs. 9-73 and 9-74), valgus deformities of the feet (Fig. 9-75), and amniotic band amputation.

Pitfalls in the diagnosis of skeletal dysplasia are appreciable. A phenocopy gives a fetus the attributes of a specific syndrome, but the cause may be another factor, such as infection, another genetic abnormality, or teratogen exposure. An example of a phenocopy is the stippling of epiphyses caused by maternal warfarin use, mimicking stippled epiphyseal skeletal dysplasia.

Two-Vessel Umbilical Cord

A single umbilical artery may be identified on transverse section and confirmed by color Doppler imaging (Fig. 9-76). Single umbilical artery may be associated with other congenital anomalies, prompting a careful anatomic survey; however, the reported anomalies do not display a consistent pattern. Lack of normal coiling is also associated with fetal abnormalities, particularly those affecting movements. It is unclear whether isolated single umbilical artery is associated with aneuploidy, nor does laterality of the absent vessel have significance. Small-for-gestational age is more common in neonates with single umbilical artery. Counseling, selective use of amniocentesis, and serial third-trimester examinations may be helpful in management.[38]

SUMMARY

As sonography nears maturity, it has shown a gratifying degree of success in fulfilling its early potential. Initial limitations have yielded to advances in technologies and techniques or have been remedied by genetic and biochemical breakthroughs. MRI is now well established as a versatile partner to US in prenatal diagnosis. The future of imaging continues to hold immense promise for continued advances in understanding and improving neonatal outcomes.

CHAPTER 10

Estimation of Fetal Well-Being

PART 1

Antepartum Fetal Surveillance

Susan E. Gerber

The primary goal of antenatal fetal surveillance is avoidance of intrauterine fetal death. In the United States, the incidence of intrauterine fetal death of 20 weeks' gestation or greater was 6.22 deaths per 1000 births in 2005. This rate has declined steadily over time, but has been relatively stable since 2003.[20] In most pregnancies, routine prenatal care provides for fetal surveillance via clinical assessment of fetal growth and activity. In certain populations with an increased risk of fetal demise, a greater degree of fetal surveillance may be warranted, however. The first part of this chapter addresses the methods used to perform such surveillance and the evidence for their use.

RATIONALE FOR SURVEILLANCE

Intrauterine fetal death may result from various etiologies, such as congenital malformations, fetomaternal hemorrhage, congenital infection, and uteroplacental failure. In many circumstances, deaths are precipitated by sudden catastrophic events, such as an abruptio placentae or cord prolapse. Such events are often unpredictable and not preventable by any form of antepartum surveillance. Women at risk for such events may not benefit from increased surveillance. Maternal cocaine use may increase the risk of abruptio placentae and intrauterine fetal death, but without underlying uteroplacental insufficiency or growth restriction, such an event would be unpredictable.

The methods commonly used for antenatal fetal surveillance rely on fetal biophysical parameters that are sensitive to hypoxemia and acidemia, such as heart rate and movement. Blood flow in the fetal-placental circulation is responsive to these conditions as well. The surveillance tools are useful in a fetus at risk for hypoxemia because of chronic uteroplacental insufficiency. It is hoped that if fetal surveillance identifies a fetus in jeopardy, the physician would have an opportunity to intervene before progressive fetal hypoxemia and acidosis lead to fetal death or to the delivery of a severely compromised neonate.

INDICATIONS FOR SURVEILLANCE

Pregnancies at increased risk for intrauterine fetal demise fall into two categories: pregnancies at risk related to maternal conditions and pregnancies at risk related to pregnancy-associated conditions. Table 10-1 lists some conditions in which antenatal surveillance should be considered. There are numerous situations in which a population is known to have an increased risk of fetal death, but the etiology is unclear. One such population is the 1% of all pregnant women who are found to have an unexplained elevated maternal serum α-fetoprotein. Although numerous studies have confirmed the elevated risk of fetal death in this population, there is no consensus on whether antenatal surveillance reduces this risk.[43] Antenatal testing in such a population is commonly performed, but it remains controversial.

PHYSIOLOGIC BASIS FOR ANTENATAL SURVEILLANCE

In experiments involving animal and human fetuses, hypoxemia and acidosis have been shown consistently to alter fetal biophysical parameters such as heart rate, movement, breathing, and tone.[7,26,35] The fetal heart rate (FHR) is normally controlled by the fetal central nervous system (CNS) and mediated by sympathetic or parasympathetic nerve impulses originating in the fetal brainstem. The presence of intermittent FHR accelerations associated with fetal movement is believed to be an indicator of an intact fetal autonomic nervous system. In a study of fetal blood sampling of pregnancies resulting in healthy neonates, Weiner and colleagues[42] established a range of normal fetal venous pH measurements. In this population, the lower 2.5 percentile of fetal venous pH was 7.37. Manning and associates[28] showed that fetuses without heart rate accelerations had a mean umbilical vein pH of 7.28 (± 0.11), and fetuses with abnormal movement had a

TABLE 10–1 Indications for Antenatal Surveillance

Maternal Conditions	Pregnancy-related Conditions
Antiphospholipid syndrome	Pregnancy-induced hypertension
Hyperthyroidism (poorly controlled)	Decreased fetal movement
Diabetes mellitus	Oligohydramnios
Cyanotic heart disease	Polyhydramnios
Systemic lupus erythematosus	Intrauterine growth restriction
Hypertensive disorders	Multiple gestation
Chronic renal disease	Post-term pregnancy
Hemoglobinopathies (hemoglobin SS, SC, or S-thalassemia)	Previous fetal demise (unexplained or recurrent risk)
	Isoimmunization (moderate to severe)
	Preterm premature rupture of membranes
	Unexplained third-trimester bleeding

From American College of Obstetricians and Gynecologists: Antepartum fetal surveillance, *ACOG Practice Bulletin 9*, Washington, DC, 1999, ACOG.

mean pH of 7.16 (± 0.08). These and similar observations were the basis for the development of antenatal fetal testing modalities that are currently in use.

NONSTRESS TEST

In most institutions, the first-line assessment tool for fetal surveillance is the nonstress test (NST). Lee and coworkers[19] first described the association between FHR accelerations and fetal movements in 1975. Monitoring for the presence or absence of both elements was proposed as a method of evaluation of fetal well-being. The NST is performed in a nonlaboring patient (as opposed to the contraction stress test [CST], in which the patient has regular uterine contractions, either spontaneously or induced). Sometimes a woman undergoing NST is found to have spontaneous contractions, adding the reassurance of a negative CST.

With the patient in a recumbent, tilted position, FHR is monitored with an external transducer for up to 40 minutes. The FHR tracing is observed for the presence of accelerations above the baseline. A reactive test is one in which there are at least two accelerations that peak 15 beats/min above the baseline and last (not at the peak) for at least 15 seconds before returning to baseline (Fig. 10-1). Most NSTs are reactive within the first 20 minutes. For tests that are not, possibly because of a fetal sleep cycle, an additional 20 minutes of monitoring may be needed. A nonreactive NST is one in which two such accelerations do not occur within 40 minutes, or in which the acceleration peaks are less than 15 beats/min.

Although the NST is noninvasive and easy to perform, it is limited by a high rate of false-positive results. Normal fetuses often have periods of nonreactivity because of benign variations such as sleep cycles. Vibroacoustic stimulation may be used safely in the setting of a nonreactive NST to elicit FHR accelerations without compromising the sensitivity of the NST.[44] In this situation, the operator places an artificial larynx on the maternal abdomen and activates the device for 1 to 3 seconds. This technique is often useful in situations in which the FHR has normal beat-to-beat variability and no decelerations, but does not show any accelerations on the NST. If the test remains nonreactive, further evaluation with a biophysical profile or CST is warranted.

CONTRACTION STRESS TEST

CST is designed to evaluate FHR response to maternal uterine contractions. The principles that are applied to the evaluation of intrapartum FHR monitoring (see Part 2) are used here. In response to the stress of the contraction, a hypoxemic fetus shows FHR patterns of concern such as late decelerations, indicating worsening hypoxemia or fetal compromise.

Similar to NST, for CST the patient is placed in a recumbent tilted position, and FHR is monitored with an external fetal monitor. FHR pattern is evaluated while the patient experiences at least three contractions lasting 40 seconds within a 10-minute period. If the patient is not contracting spontaneously, contractions may be induced with nipple stimulation or intravenous oxytocin. If no late or significant

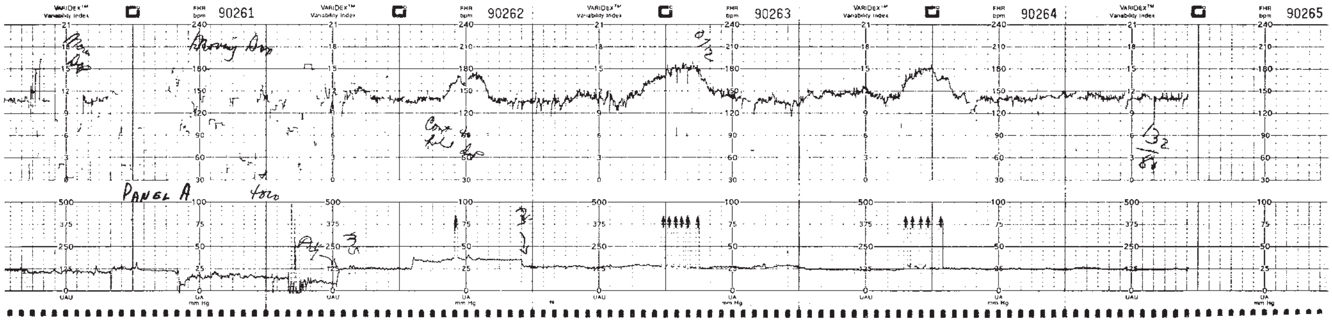

Figure 10–1. Reactive nonstress test, showing accelerations occurring with fetal movement. Note the arrows on the contraction channel. *(From Freeman R, Garite T:* Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins.)*

variable decelerations are noted on FHR tracing, CST is considered to be negative. If there are late decelerations after at least 50% of the contractions, CST is positive. If late decelerations are present less than 50% of the time, or if significant variable decelerations are present, the test is considered to be equivocal. Contraindications to the performance of CST include clinical situations in which labor would be undesirable (e.g., placenta previa or previous classic cesarean section).

BIOPHYSICAL PROFILE

The biophysical profile was developed by Manning and associates[27] as an alternative tool to other methods of antenatal surveillance to evaluate fetal well-being. As originally described, it combines NST with four components evaluated by ultrasonography. In a 30-minute period, the following observations are sought:

1. Fetal breathing movements (one or more episodes lasting at least 30 seconds)
2. Fetal movement (three or more discrete body or limb movements)
3. Fetal tone (one or more episodes of active extension with return to flexion of a limb or trunk, or the opening and closing of a fetal hand)
4. Amniotic fluid volume (originally described as a single vertical pocket of ≥1 cm, subsequently modified to ≥2 cm) (Fig. 10-2)
5. Reactive NST

Each component is assigned a score of 2 if present and 0 if absent. A combined score of 8 or 10 indicates fetal well-being. A score of 6 is considered to be equivocal, and it usually merits delivery if the pregnancy is at term, or repeat testing in 24 hours if the pregnancy is preterm. A score of 4 or less is considered to be abnormal, and delivery is warranted except for extenuating circumstances. The biophysical profile also has been analyzed with the four ultrasound parameters alone, and when all are present, it has been shown to have a false-negative rate similar to the full biophysical profile.[25]

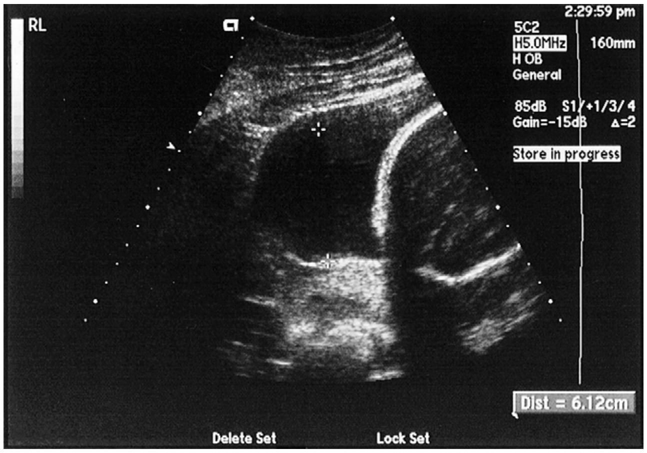

Figure 10–2. Ultrasound image of the maximal vertical pocket measured as part of either the biophysical profile or the amniotic fluid index. Note the absence of umbilical cord in the measured pocket.

AMNIOTIC FLUID VOLUME ASSESSMENT

Amniotic fluid volume is commonly estimated on ultrasound scan via one of two methods. The amniotic fluid index is calculated by measuring the maximal vertical pockets of fluid (without loops of umbilical cord) in each of the four quadrants of the maternal abdomen (see Fig. 10-2). Alternatively, the single deepest vertical pocket of fluid is measured. Decreased amniotic fluid volume, or oligohydramnios, is typically defined as either an amniotic fluid index of 5 cm or less or no measurable vertical pocket of fluid greater than 2 cm. Although both measurement techniques are equally effective in estimating amniotic fluid volume, both have relatively poor sensitivity for the detection of oligohydramnios.[22]

In most circumstances, oligohydramnios is thought to reflect fetal compromise. A decrease in placental perfusion results in decreased blood flow and consequently decreased oxygen delivery to the fetus. There is also decreased renal perfusion by the preferential shunting of blood to the fetal brain. Decreased renal perfusion results in decreased fetal urine output, which leads to a decreased amniotic fluid volume.

Oligohydramnios is commonly associated with post-term pregnancy, fetal growth restriction, maternal hypertension, and preeclampsia. In various clinical scenarios, oligohydramnios has been found to be associated with an increased risk of preterm delivery, low or very low birthweight, low Apgar scores, intrauterine fetal death, meconium-stained amniotic fluid, admissions to a neonatal intensive care unit, and cesarean delivery for nonreassuring fetal status.[3,18,21] In a term pregnancy, oligohydramnios is considered an indication for delivery. In a preterm pregnancy, immediate delivery may be undesirable, and in such cases increased surveillance is warranted. In a preterm fetus with oligohydramnios, delivery is indicated for nonreassuring or abnormal fetal surveillance, or when there is no interval growth on ultrasound.

MODIFIED BIOPHYSICAL PROFILE

Although the NST reflects the present fetal neurologic status and oxygenation, amniotic fluid volume is a better measure of chronic placental function. Some authors have favored the use of the modified biophysical profile, which consists of the combination of NST and amniotic fluid index. In a study of 15,482 women undergoing antenatal testing, Miller and colleagues[32] found modified biophysical profile to have a lower false-negative rate than NST. An abnormal result may be followed by a full biophysical profile or a CST.

DOPPLER FLOW VELOCIMETRY

Ultrasonography of fetal and maternal blood flow is also used to evaluate the health of a pregnancy. The most commonly studied vessel is the fetal umbilical artery. Doppler measurements of the pulsatile blood flow in the umbilical arteries directly reflect the status of the fetomaternal circulation (Fig. 10-3). A progressive decrease in placental function or blood flow is thought to manifest with an increased resistance to flow as evidenced by a diminution in the diastolic flow and eventual absence or reversal of flow during diastole in the fetal vessels. In clinical practice, commonly measured

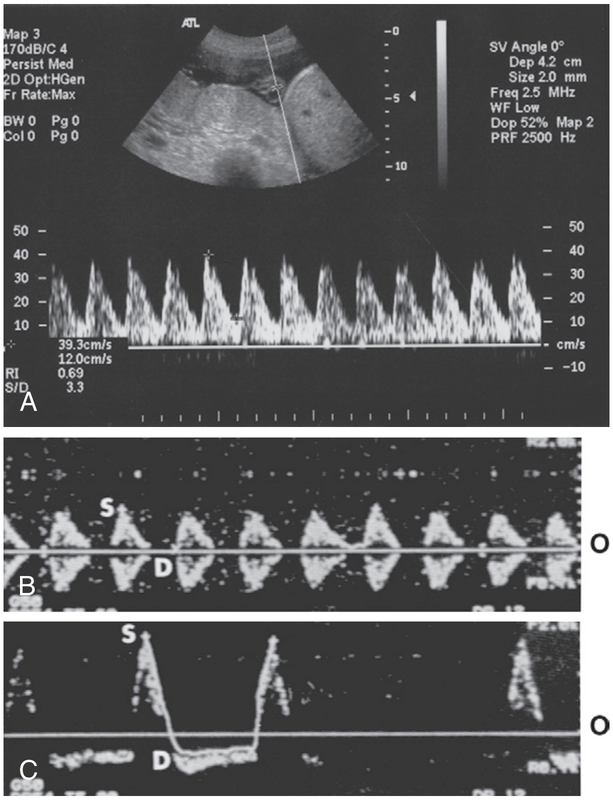

Figure 10–3. Composite images of three studies of fetal umbilical arterial velocimetry, ranging from normal to markedly abnormal. **A**, Normal velocimetry pattern. **B**, Absent diastolic flow, indicating increased placental resistance. **C**, Reversal of diastolic flow, indicating worsening placental function. D, diastolic velocity; S, systolic velocity.

indexes include the systolic/diastolic (S/D), ratio resistance index [(S-D)/S], and pulsatility index [(S-D)/A].

Doppler flow velocimetry of the fetal umbilical artery has been studied in numerous at-risk populations. Pregnancies with suspected intrauterine growth restriction have been extensively studied, and there is evidence that in this population, abnormal blood flow in the umbilical artery is associated with increased risk of perinatal morbidity and mortality.[39] A Cochrane review of 11 randomized trials showed a trend toward decreased perinatal mortality with the use of Doppler assessment of the umbilical artery in high-risk pregnancies.[36] The use of umbilical artery Doppler flow velocimetry as a primary testing method results in fewer antenatal tests and less intervention with similar neonatal outcome compared with pregnancies monitored by NST.[17] There is also evidence that abnormal umbilical artery blood flow velocimetry precedes FHR abnormalities by a median of 7 days.[2]

Doppler flow velocimetry has also been studied in other vessels including the fetal ductus venosus, fetal middle cerebral artery, and maternal uterine artery. Evaluation of the fetal ductus venosus remains controversial. In the setting of severe preterm fetal growth restriction, abnormal flow in the ductus venosus has been shown to be independently associated with perinatal morbidity and mortality.[5,6,12] The utility of this assessment has been questioned, however, given an apparent brief latency between abnormality and fetal compromise and poor predictive values, particularly at early gestational ages.[15]

In a high-risk cohort, the presence of abnormal flow velocity or "notching" in the maternal uterine artery at 22 to 24 weeks' gestation has been associated with an increased risk of subsequent preeclampsia and fetal growth restriction.[11] More recent studies have also shown a possible association with fetal growth restriction for this finding in the first trimester.[31] Controversy remains regarding the optimal timing of the evaluation, and the specific abnormalities ("notch" versus abnormal indexes) that are most predictive of adverse outcome.[30]

Doppler flow velocimetry of the fetal umbilical artery has not been found to convey any benefit in a low-risk population.[1] Selective use of Doppler velocimetry for traditional indications within a general population has not been shown to result in decreased maternal hospitalization or improved neonatal outcome.[38] Uterine artery Doppler flow velocimetry has also been shown to have limited predictive value in a low-risk population.[10]

Fetal cerebral arteries show altered blood flow in the setting of hypoxemia. In certain pregnancies, such as those complicated by isoimmunization, the fetus is at risk for the development of severe anemia. Traditionally, standard practice has been to evaluate such pregnancies with serial amniocentesis or cordocentesis or both to determine if a fetus is at risk for intrauterine death owing to anemia. Mari[29] described the use of Doppler velocimetry of the fetal middle cerebral artery to evaluate fetuses at risk for anemia because of maternal isoimmunization. The peak systolic velocity of the middle cerebral artery is inversely correlated with fetal hemoglobin, and the measurement provides a noninvasive means of detecting an increased risk of fetal anemia (Fig. 10-4). These results have been shown to have equal or greater sensitivity in the detection of severe fetal anemia and have replaced the use of amniocentesis for this diagnosis in many centers.[37]

Ultrasound image of the fetal cerebral vasculature, with Doppler visualization of the middle cerebral artery and measurement of the peak systolic velocity. *(From Dukler D et al: Noninvasive tests to predict fetal anemia: a study comparing Doppler and ultrasound parameters,* Am J Obstet Gynecol *188:1310, 2003.)*

INTERPRETATION OF TEST RESULTS

The realistic goal of antepartum testing is to decrease the risk of intrauterine fetal demise or perinatal mortality in the tested population so that it approaches the rate for a low-risk population without an excessive or unacceptable false-positive rate that may result in unnecessary intervention. When corrected for congenital anomalies and unpredictable causes of intrauterine death, the rate of stillbirth in the tested population (after antepartum testing with normal results) has been reported to be approximately 1.9 per 1000 for NST, 0.3 per 1000 for CST, 0.8 per 1000 for biophysical profile, and 0.8 per 1000 for modified biophysical profile.[1] These rates are comparable to the rates for the risk of fetal death in a low-risk population.

The false-positive rate is more difficult to ascertain because a positive test usually results in obstetric intervention, significantly decreasing the likelihood of intrauterine death. One study showed, however, that 90% of nonreactive NSTs are followed by a negative CST result, consistent with a high false-positive rate for NST.[13] A study of CSTs in which physicians were blinded to the results found that in 61% of patients with positive tests there were no fetal late decelerations in labor, no low Apgar scores, and no significant neonatal morbidity.[41] Manning and associates[24] reported on a cohort of 913 infants delivered after biophysical profile score of 6 or less. Nearly 40% of infants with scores of 6 showed no markers of fetal compromise at delivery, as defined by fetal distress in labor, admission to the neonatal intensive care unit, a 5-minute Apgar score of 7 or less, or an umbilical cord pH less than or equal to 7.20. There was a significant inverse linear association, however, between biophysical profile score and these markers, and all fetuses with scores of 0 had at least one of these markers at delivery.

In a clinically stable situation, reassuring tests (reactive NST, negative CST, and biophysical profile of 8 or 10) are considered reliable for 1 week, and so testing is usually performed on a weekly basis. Labile conditions may merit more frequent testing; the frequency is left to the discretion of the physician. If the indication for testing is not a persistent one (e.g., maternal perception of decreased fetal movement), there is no evidence to support the continuation of antenatal testing. In certain high-risk populations, the false-negative rate of NST may be unacceptably high. The stillbirth rate within 1 week of a reactive NST is markedly higher for patients with diabetes mellitus (14 per 1000) and fetal growth restriction (20 per 1000).[4] Similarly, elevated results have been reported for patients with prolonged gestations.[33] Boehm and coworkers[8] found that the stillbirth rate decreased from 6.1 per 1000 to 1.9 per 1000 in their high-risk population when the frequency of testing was changed from once weekly to twice weekly. For this reason, testing twice weekly may be appropriate in certain populations, such as those described.

FETAL GESTATIONAL AGE AND ANTENATAL SURVEILLANCE

FHR variability and reactivity vary with gestational age. Before 28 weeks of gestation, 50% of all NSTs may not be reactive. From 28 to 32 weeks of gestation, approximately 15% of normal fetuses have nonreactive NSTs.[1] Although fetal breathing movements and body movements are noted to decrease before the onset of spontaneous labor,[9] the biophysical parameters that make up the biophysical profile score are present at early gestational ages, and are useful in the evaluation of a very premature fetus.

The optimal gestational age at which to begin antenatal surveillance depends on the clinical condition. In making this decision, the physician must weigh the risk of intervention at a premature gestational age against the risk of intrauterine fetal death. The American College of Obstetricians and Gynecologists recommends initiating testing at 32 to 34 weeks' gestation for most at-risk patients, with the acknowledgment that some situations may warrant testing earlier at 26 to 28 weeks of gestation.[1]

CLINICAL CONSIDERATIONS

Many clinical situations not related to fetal well-being temporarily affect the interpretation of antenatal surveillance techniques. Maternal cigarette smoking and alcohol ingestion decrease fetal movement, breathing, and heart rate reactivity.[14,16,23] Commonly used maternal medications such as opioids and corticosteroids significantly decrease various fetal biophysical parameters, including movement, breathing, and heart rate reactivity, without compromising neonatal outcome.[34,40] Maternal medical conditions, such as an acute asthma exacerbation or diabetic ketoacidosis, may result in nonreassuring fetal surveillance, including worrisome biophysical profile scores. Delivery of a mother in such an unstable condition is dangerous and undesirable. The improvement or elimination of such conditions usually results in an improvement in fetal status. The improved fetal status is accompanied by an improvement in antenatal testing results, and it negates the need for a premature delivery.

SUMMARY

In high-risk populations at increased risk of perinatal mortality, antenatal fetal surveillance plays a large role in prenatal care. Pregnancies at risk for progressive deterioration of placental function leading to fetal hypoxemia and acidosis are most likely to benefit from the methods currently in use. The various modalities, including NST, CST, biophysical profile, and Doppler velocimetry, rely on fetal biophysical parameters that are significantly associated with the presence or absence of fetal hypoxemia. Because all tests are associated with a false-positive rate, each test result should be interpreted within the clinical context presented by the patient.

PART 2

Evaluation of the Intrapartum Fetus

Susan E. Gerber and Barrett K. Robinson

It has long been recognized that the process of labor and delivery is metabolically stressful for the fetus. Most healthy fetuses are able to tolerate this challenge with no adverse effect. The purpose of intrapartum fetal monitoring is to identify fetuses for whom the stresses of labor induce such significant acidemia and hypoxemia that permanent harm would be risked if delivery were not imminent. Identification of this risk should allow physicians to intervene and prevent intrapartum death or neonatal damage. This part addresses the methods currently in use to accomplish this goal and discusses their limitations.

FETAL HEART RATE MONITORING

In the United States, the primary method used for intrapartum surveillance is the evaluation of FHR. Continuous electronic FHR monitoring, which was introduced in the 1970s, typically is used. Although electronic FHR monitoring has never been shown to result in better neonatal outcomes compared with intermittent auscultation of FHR,[1] 85% of all deliveries were managed with electronic FHR monitoring in 2003.[12]

During labor, uterine contractions produce increased intrauterine pressure, decreased maternal uterine artery blood flow, and intermittent reduction of placental gas exchange. Over the course of a normal labor, all fetuses show a progressive decrease in oxygenation and pH.[13] A fetus is not at risk for permanent neurologic damage, however, until the levels of hypoxia and acidosis become extreme.

The underlying rationale for intrapartum FHR monitoring is the same as the rationale behind antepartum surveillance with NST or CST. FHR is normally controlled by the fetal CNS, and the fetal CNS is sensitive to hypoxia. Experimentally induced hypoxia is associated with consistent and predictable changes in FHR. Most studies have been performed in fetal sheep, with intermittent cord occlusion used to produce hypoxia.[20] These changes, when present in the FHR tracing, are thought to be indicators of fetal hypoxia.

Electronic FHR monitoring may be performed externally or internally. Telemetry units are available, so that a patient need not be confined to a bed to be monitored. Most external monitors use a Doppler device with computerized logic to interpret and count the Doppler signals. Internal FHR monitoring may be performed in circumstances in which external monitoring is unreliable or not feasible (e.g., maternal obesity). Internal monitoring uses an electrode that is attached to the fetal scalp. The FHR tracing is transmitted to a monitor and interpreted visually by the medical team.

INTERPRETATION OF FETAL HEART RATE PATTERNS

Baseline Fetal Heart Rate

Baseline FHR is the average FHR rounded to increments of 5 beats/min during a 10-minute segment, excluding periodic or episodic changes, periods of marked variability, or baseline segments that differ by more than 25 beats/min. In any given 10-minute window, the minimal baseline duration must be at least 2 minutes, or the baseline is considered indeterminate. In cases in which the baseline is indeterminate, the previous 10-minute window should be reviewed and used to determine the baseline. A normal FHR baseline rate ranges from 110 to 160 beats/min. If the baseline FHR is less than 110 beats/min, it is termed *bradycardia*. If the baseline FHR is greater than 160 beats/min, it is termed *tachycardia*.

The initial response of FHR to intermittent hypoxia is deceleration, but baseline tachycardia may develop if the hypoxia is prolonged and severe. Tachycardia may also be associated with conditions other than hypoxia, such as maternal fever, intra-amniotic infection, thyroid disease, the presence of medication, and cardiac arrhythmia (Fig. 10-5).

Fetal Heart Rate Variability

The presence of baseline FHR variability is a useful indicator of fetal CNS integrity. Variability is defined as fluctuations in FHR baseline of two cycles per minute or greater, with irregular amplitude and inconstant frequency. Moderate FHR variability is strongly associated (98%) with an umbilical pH greater than 7.15.[16] In most cases, normal FHR variability provides reassurance about fetal status. In the absence of maternal sedation, magnesium sulfate administration, long-term beta-blocker treatment, or extreme prematurity, decreased variability, or

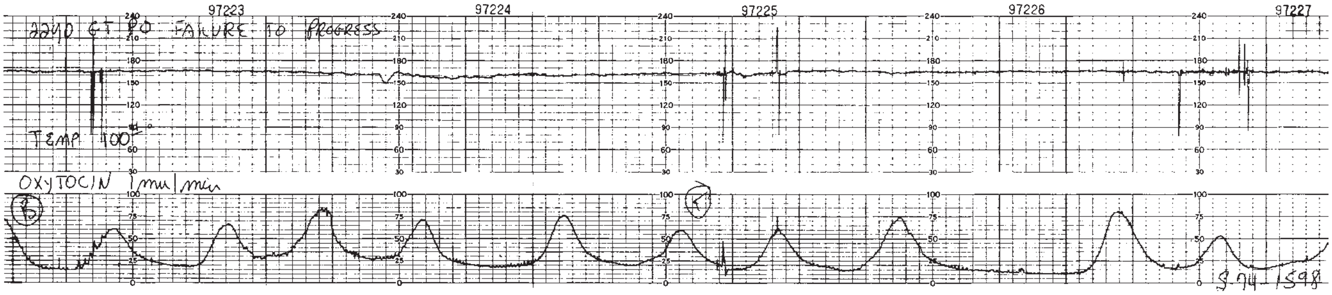

Figure 10–5. Fetal tachycardia, with a baseline fetal heart rate of 165 beats/min. This was in the setting of a maternal fever. *(From Freeman R, Garite T:* Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 70.)*

flattening of FHR baseline, may serve as a barometer of the fetal response to hypoxia. Because decreased variability or flattening is presumed to be a CNS response, in most situations decelerations of FHR precede the loss of variability, indicating the cause (Fig. 10-6).

FHR variability is visually assessed as the amplitude of the peak to trough in beats per minute as follows:

Amplitude range	Classification
Undetectable	Absent
1 to 5 beats/min	Minimal
6 to 25 beats/min	Moderate
>25 beats/min	Marked

Accelerations

Accelerations in FHR are periodic elevations above the baseline, and they are usually associated with fetal movement. The presence of FHR accelerations during labor is always reassuring, as it is in a nonlaboring patient. The absence of accelerations during labor is not reflective of fetal hypoxemia, however.

Decelerations

Decelerations in FHR are episodic decreases below the baseline. They are mediated by the fetal chemoreflex in response to hypoxia, presumably to reduce the myocardial work and oxygen requirements. Decelerations are quantified by the depth of the nadir in beats per minute and the duration from the beginning to the end of the deceleration. Decelerations are defined further as "recurrent" if they occur with at least 50% of the contractions. Decelerations are categorized by virtue of their morphology and timing, and this classification is thought to identify the underlying mechanism responsible for the decelerations.

Three types of decelerations were initially described by Hon and colleagues in 1967.[9] Early decelerations are shallow and symmetric, gradual in onset and recovery, and associated with a contraction such that the nadir of the deceleration occurs at the same time as the peak of the contraction. They are thought to be caused by the compression of the fetal head in active labor and are associated with a favorable fetal outcome (Fig. 10-7).

Variable decelerations are the most common form of decelerations in labor. They are typically associated with an abrupt onset and abrupt return to baseline. They vary in shape, depth, and duration, although they usually coincide with a contraction. They are also frequently preceded and followed by small accelerations in FHR (Figs. 10-8 and 10-9). Variable decelerations are often associated with compression of the umbilical cord and with favorable outcome, particularly if they are brief, shallow, and not recurrent. Repetitive prolonged and deep variable decelerations may result in progressive hypoxemia and acidemia.

Late decelerations, by contrast, have a more gradual onset and return to baseline—typically 30 seconds or more from onset to nadir. The onset, nadir, and recovery of the deceleration occur after the onset, peak, and end of the contraction (Fig. 10-10). Although an occasional late deceleration is not indicative of fetal compromise, recurrent late decelerations are considered to be nonreassuring and cause for further evaluation, remediation, or delivery.

A sinusoidal heart rate pattern consists of a regular oscillation of the baseline variability, in a smooth undulating pattern. This pattern typically lasts at least 10 minutes, has a relatively fixed period of three to five cycles per minute, and has an amplitude of 5 to 15 beats/min above and below the baseline (Fig. 10-11). This pattern is quite rare, but can be associated with severe chronic anemia or severe hypoxia and acidosis.

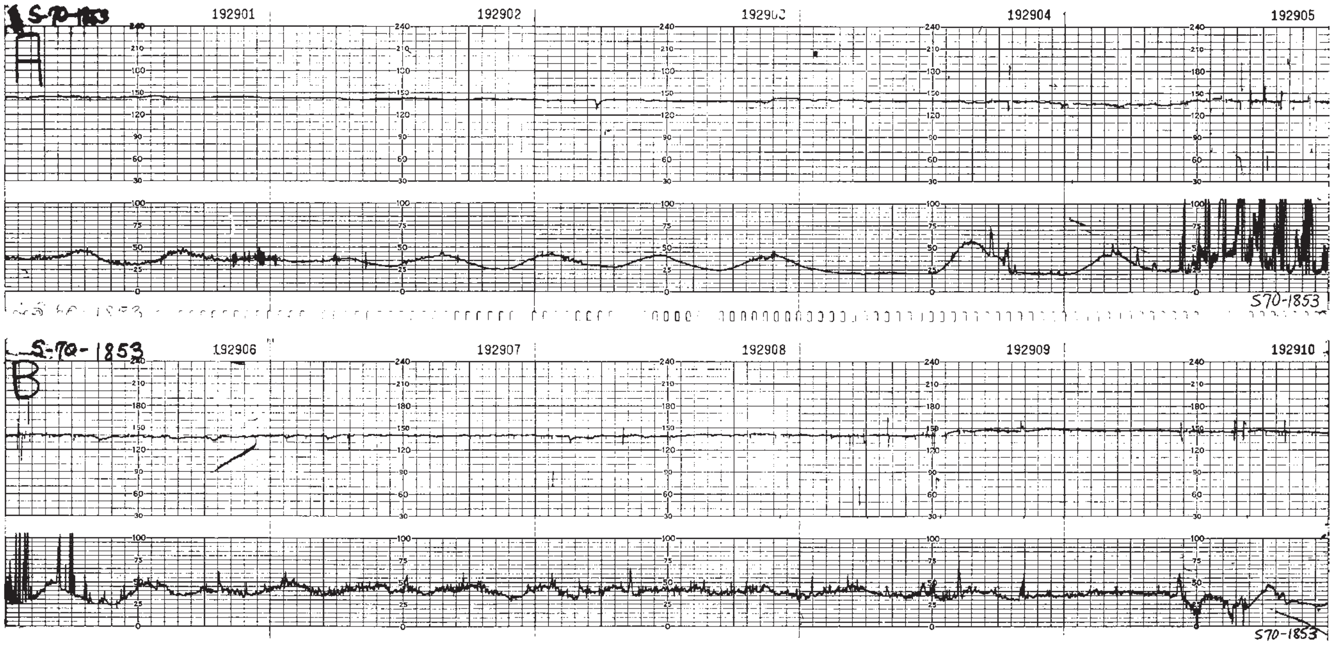

Figure 10–6. Abnormal (absent) fetal heart rate (FHR) variability. Because there are no decelerations present, this would qualify as a category II FHR tracing. *(From Freeman R, Garite T:* Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 138.)*

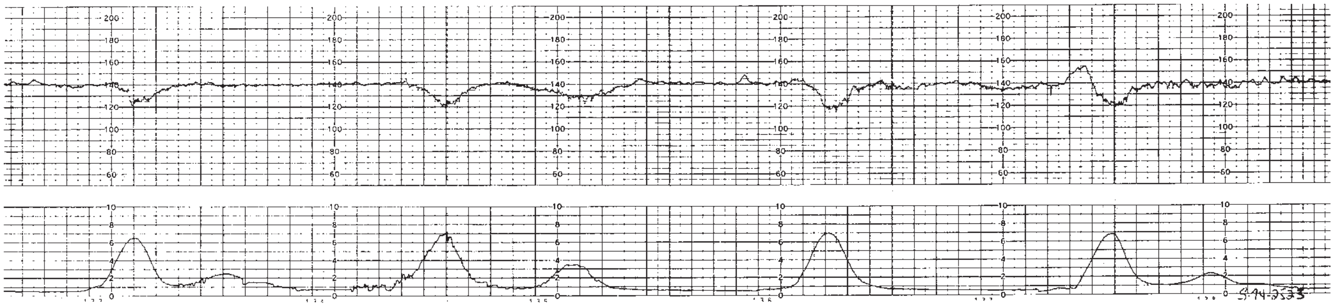

Figure 10–7. Early decelerations. Note the way in which the decelerations appear to “mirror” the uterine contractions. (*From Freeman R, Garite T*: Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 74.)*

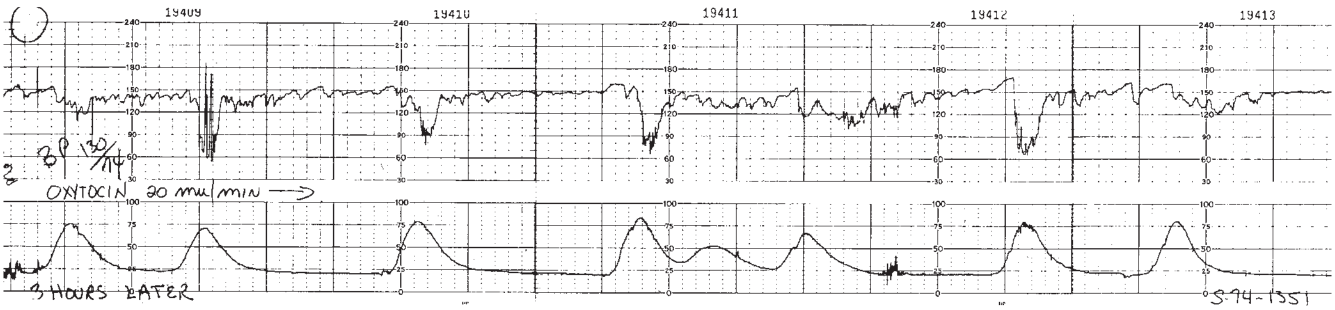

Figure 10–8. Variable decelerations. Note the normal fetal heart rate baseline and variability between the decelerations. (*From Freeman R, Garite T*: Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 78.)*

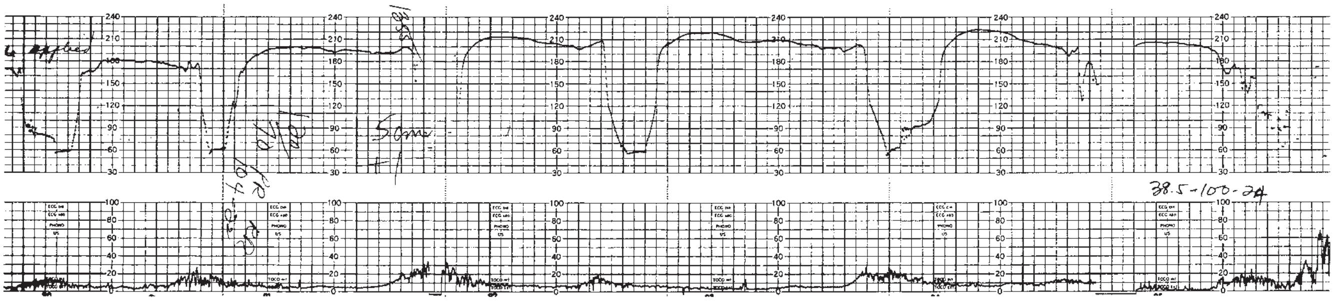

Figure 10–9. Variable decelerations. In contrast to Figure 10–8, note the tachycardic fetal heart rate (FHR) baseline and absent variability between the decelerations. Also note the prolonged FHR “overshoot” in the middle portion of the panel. This FHR tracing is more concerning for the presence of fetal hypoxia and acidosis, and would be considered category III.

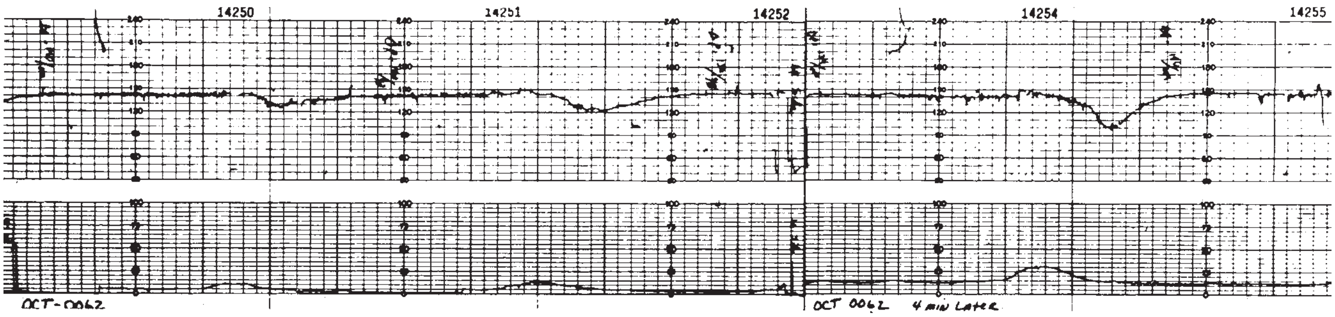

Figure 10–10. Late decelerations. Note the timing of the onset, nadir, and recovery of the deceleration, which occur after the onset, peak, and end of the contraction. (*From Freeman R, Garite T*: Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 201.)*

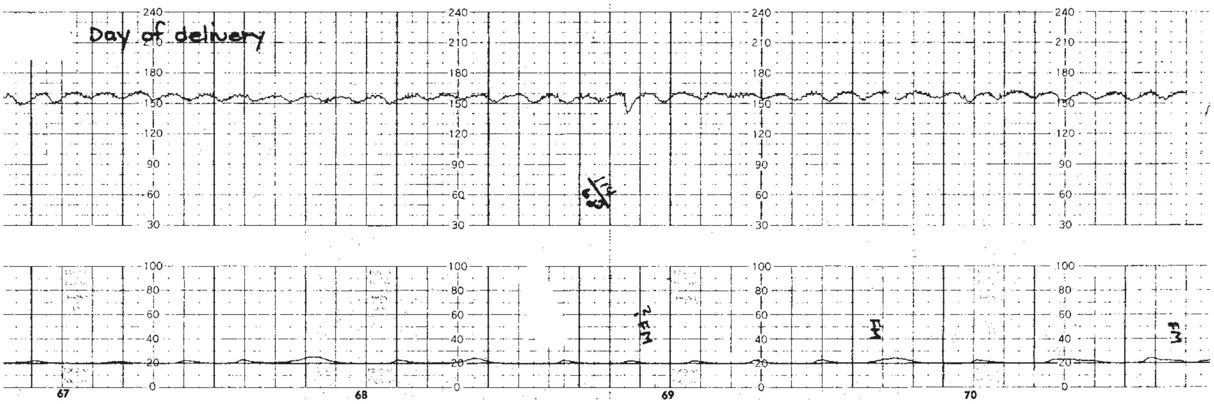

Figure 10–11. Sinusoidal fetal heart rate pattern. This fetus was severely anemic and hydropic because of maternal Rh isoimmunization. *(From Freeman R, Garite T:* Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 166.)*

INTERPRETATIVE SYSTEMS FOR CLASSIFICATION OF FETAL HEART RATE PATTERNS

Since its introduction, the utility of electronic fetal monitoring has been limited by the subjective nature of its interpretation. Although many interpretative systems exist for FHR tracings, the 2008 National Institutes of Child Health and Human Development (NICHHD) workshop dealing with Standardization of Nomenclature for Intrapartum Electronic Fetal Monitoring, jointly sponsored by NICHHD, the American College of Obstetricians and Gynecologists, and the Society for Maternal Fetal Medicine, had certain criteria. The system selected by the workshop is one that is evidence-based, simple, and applicable to clinical practice.[11]

The FHR response is a dynamic process that requires frequent reassessment. Categorization of a tracing is limited to the time period being assessed, and over time FHR tracings commonly migrate from one category to another. FHR tracing patterns provide information on the *current* acid-base status of the fetus and cannot predict the development of cerebral palsy.

The two FHR findings that reliably predict the absence of acidemia are accelerations and moderate variability. Accelerations are defined by a peak of 15 beats/min or greater above the baseline, with the acceleration lasting 15 seconds or more, but less than 2 minutes from the onset to the return to the previously determined baseline. In pregnancies of less than 32 weeks' gestational age, accelerations are defined as having a peak 10 beats/min or greater above the baseline and a duration of 10 seconds or more. Although either fetal accelerations or moderate FHR variability reliably predicts the absence of acidemia, the absence of accelerations, the presence of minimal variability, or the presence of absent variability do not reliably predict the presence of fetal hypoxemia or metabolic acidemia. The significance of marked variability (formerly described as saltatory) is unclear. Although the entire associated clinical circumstances must always be taken into account, the 2008 NICHHD workshop simplified categorization and interpretation of FHR tracings into a three-tier system described next.[11]

Three-Tier Fetal Heart Rate Interpretation System[17]

CATEGORY I

Normal tracings, which are strongly predictive of normal fetal acid-base status at the time of observation and can be followed in a routine manner without any specific action required, include all of the following:

- Baseline rate of 110 to 160 beats/min
- Moderate variability
- Absence of any late or variable decelerations
- Early decelerations may or may not be present
- Accelerations may or may not be present

CATEGORY II

Indeterminate tracings, although not predictive of abnormal fetal acid-base status, cannot be classified as category I or III, and require evaluation and continued surveillance and reevaluation. These tracings are frequently encountered in clinical care and include any of the following:

- Baseline rate
  - Tachycardia
  - Bradycardia not accompanied by absent baseline variability
- Baseline FHR variability
  - Minimal baseline variability
  - Absent baseline variability not accompanied by recurrent decelerations
  - Marked baseline variability
- Absence of induced accelerations after fetal stimulation (e.g., scalp stimulation, vibroacoustic stimulation, direct fetal scalp sampling, transabdominal halogen light)
- Periodic or episodic decelerations
  - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
  - Prolonged deceleration 2 minutes or more, but less than 10 minutes
  - Recurrent late decelerations with moderate baseline variability
  - Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," or "shoulders"

CATEGORY III

Abnormal tracings, which are predictive of abnormal fetal acid-base status at the time of observation, require prompt evaluation and initiation of expeditious attempts to resolve the abnormal FHR pattern, such as provision of maternal oxygen, change in maternal position, discontinuation of labor stimulation, treatment of maternal hypotension, or additional efforts. These tracings include *either*:

- Absent baseline FHR variability along with *any* of the following
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

Standardization of terminology and subsequent categorization into one of three tiers should aid providers when attempting to decide whether the patterns suggest a lack of fetal acidemia or alternatively require intervention. Despite numerous studies having shown that interobserver and intraobserver variability is high when FHR tracings are reviewed,[7,15] there is a common consensus that normal tracings classified as category I indicate an absence of fetal acidemia and are reassuring.[9-11] Acidemia may be present in one of four fetuses with abnormal, nonreassuring category III FHR tracings.[16] Although expeditious action is indicated to resolve the concerning aspects of the abnormal tracing or to consider moving toward delivery, because of the low prevalence of intrapartum fetal asphyxia, abnormal tracings have a well-recognized false-positive rate greater than 90%.[9]

Patients with indeterminate tracings—classified as category II—may ultimately be the most difficult to manage in clinical practice. A mainstay of the recommended strategy is close, continuous evaluation and assessment. These tracings may ultimately fit criteria for normal, reassuring category I tracings as time passes or after subsequent evaluative strategies, at which point confidence in the nonacidemic status of the fetus may be gained. Alternatively, indeterminate tracings may ultimately meet the criteria for abnormal category III tracings, in which case the imperative to resolve concerning aspects or move expeditiously toward delivery becomes clear.[17] Because of the potential uncertainty inherent in these nonpredictive tracings, a call has been issued for investigational research focusing on the relationship between such tracings and clinical outcomes.[11]

EVALUATION AND MANAGEMENT OF NONREASSURING FETAL HEART RATE PATTERNS

The evaluation of a nonreassuring FHR pattern begins with a search for an etiology that would require immediate delivery. A prolonged deceleration might be the result of an umbilical cord prolapse, or an acute placental abruption or uterine rupture (Fig. 10-12). In the absence of such events, one must search for a remediable cause of the nonreassuring FHR tracing. Repetitive late decelerations or fetal bradycardia may result from contractions that are too frequent in timing or from uterine hyperstimulation (Fig. 10-13). Without adequate recovery between contractions, the fetus is unable to tolerate the episodes of hypoxemia and becomes progressively acidotic. When the hyperstimulation is stopped, either by discontinuing or decreasing an oxytocin infusion or by administering a betamimetic agent, the fetal status typically improves, however, and this pattern resolves.

Nonreassuring FHR patterns may also be seen in the setting of maternal conditions such as severe anemia, hypotension, hypoxemia (e.g., in the setting of an acute respiratory event such as an asthma attack), or acidosis (e.g., an episode of diabetic ketoacidosis). Improvement of the maternal status typically results in the return of a reassuring FHR pattern. Not only is delivery not required in such a setting, but it is often undesirable because of the fragile maternal medical condition.

Maternal position in labor can affect the FHR tracing as the supine position decreases uterine blood flow and placental perfusion. Repositioning a patient to the lateral recumbent position can often reverse a nonreassuring FHR pattern with no other intervention. Supplemental oxygen therapy for the mother is often administered and thought to increase fetal oxygen levels, although there are no data on the efficacy or safety of this therapy.[9] When recurrent variable decelerations are present, amnioinfusion, in which fluid is infused into the uterine cavity, has been shown to decrease the rate of variable decelerations and cesarean delivery for nonreassuring fetal status.[8]

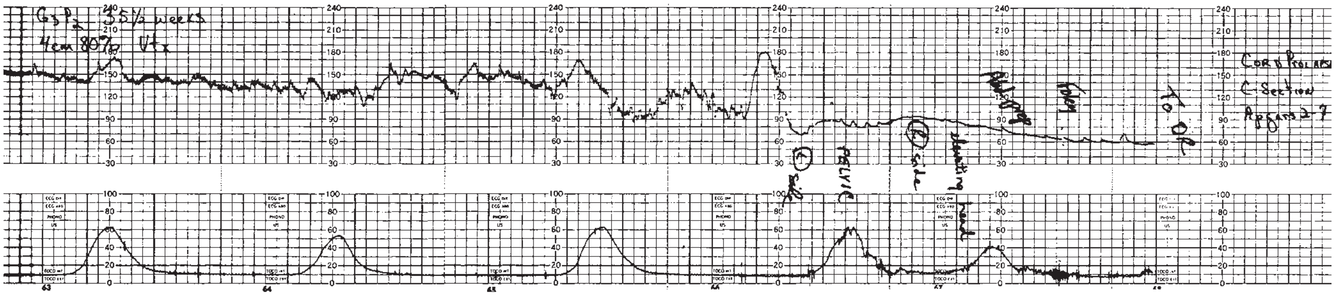

Figure 10–12. Prolonged deceleration associated with acute prolapse of the umbilical cord. Note the reassuring fetal heart rate tracing leading up to the deceleration, indicating an acute event. *(From Freeman R, Garite T:* Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 83.)*

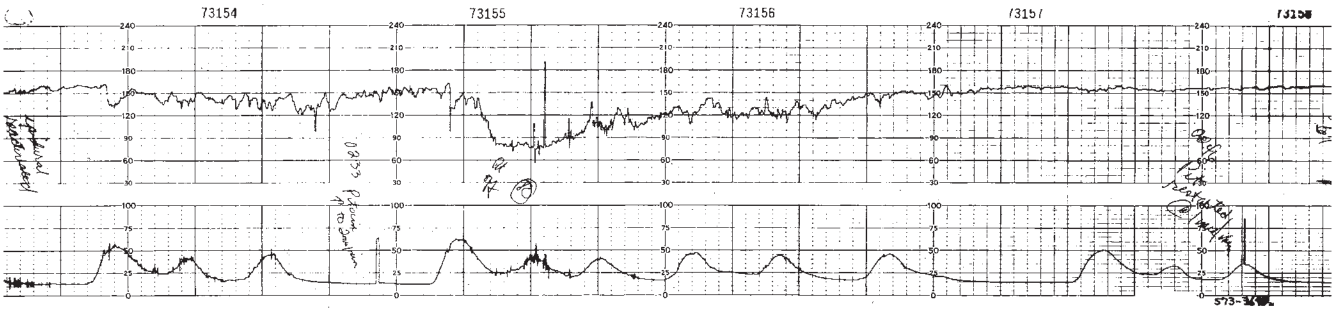

Figure 10–13. Prolonged deceleration associated with uterine hyperstimulation. Note the recovery of the deceleration after discontinuation of the oxytocin infusion. *(From Freeman R, Garite T:* Fetal heart rate monitoring, *Baltimore, 1981, Williams & Wilkins, p 85.)*

Interpretation of FHR baseline must take into account any maternal medication administration. Numerous commonly used medications, such as magnesium sulfate, corticosteroids, are known to result in decreased FHR variability and narcotics. Diminished variability in this setting may not reflect fetal hypoxia, but other criteria must be used for evaluation of the fetal status.

The clinical context of the fetus must also be considered when evaluating the FHR tracing because not all fetuses have the same ability to tolerate a normal labor. A preterm fetus or fetus with growth restriction typically has less placental reserve and is more susceptible to a rapid progression in hypoxia and metabolic acidosis. Similarly, pregnancies complicated by conditions such as abruptio placentae, chorioamnionitis, and preeclampsia may also present lowered fetal reserve because of impaired placental gas exchange.

When faced with a nonreassuring FHR tracing and no identifiable cause, the clinician may choose to seek reassurance from various other tests. Additional testing is often done because of the high false-positive rate for electronic fetal monitoring in an attempt to avoid the morbidity of an unnecessary cesarean section or operative vaginal delivery. An acceleration in FHR after vibroacoustic stimulation or fetal scalp stimulation with a digital examination provides reliable reassurance of a normal fetal pH and allows labor to continue.[4,18] Blood sampling taken from the fetal scalp has also been used to assess the fetal pH directly, although this technique is used less frequently today.

LIMITATIONS OF FETAL HEART RATE MONITORING

The introduction of electronic FHR monitoring in the 1970s was expected to reduce significantly the number of cases of intrapartum asphyxia leading to death or permanent neurologic damage and, in its most severe form, cerebral palsy. The rates of intrapartum fetal death have significantly declined since the 1970s.[19] The rates of cerebral palsy have not decreased in developed countries in the past 30 years, however.[5] There are multiple reasons for these findings. Although cerebral palsy was previously thought to result primarily from intrapartum asphyxia, it is now recognized that intrapartum events are responsible for only a small fraction of this condition, with most cases caused by antenatal events that occur before the onset of labor. Despite continual efforts at standardization, interpretation of FHR tracing is subjective and prone to significant interobserver and intraobserver variation.[7,15] This technique is fraught with false-positive results and poor positive predictive value. Using cerebral palsy as an endpoint, one study found the positive predictive value of FHR monitoring to be 0.14%.[14]

The rate of cesarean delivery in the United States has increased dramatically during this time frame, to nearly 32% in 2007.[6] Many experts attribute this increase to the introduction of FHR monitoring and the increasingly contentious medicolegal environment. Despite the lack of evidence to support long-term benefit from its use, electronic FHR monitoring is likely to remain the most common form of intrapartum fetal assessment in the near future.

NEW TECHNOLOGIES

Given the limitations of the current system, additional technologies have been developed in an attempt to identify the at-risk fetus better without unnecessarily intervening and introducing iatrogenic morbidity and mortality. In 2000, the U.S. Food and Drug Administration granted conditional approval of the OxiFirst Fetal Oxygen Saturation Monitoring System for use as an adjunct to traditional electronic FHR monitoring. This device was designed to provide continuous monitoring of the fetal oxygen saturation with a sensor placed against the fetal cheek. A multicenter randomized trial including 5341 women showed no significant difference in cesarean delivery rates or neonatal outcome when this technique was compared with traditional monitoring.[3] More recently, attention has turned to the use of a fetal electrocardiogram, with specific focus on the ST segment. European studies have evaluated the use of an automatic ST waveform analyzer in conjunction with traditional electronic fetal monitoring, and indicate potential benefits, but further research is warranted.[2]

SUMMARY

Despite the inherent stress of labor, most fetuses are able to tolerate the transient episodes of hypoxemia without harm. Rarely, the process of labor and delivery places a fetus in jeopardy of long-term neurologic damage or death as a result of profound hypoxemia and metabolic acidosis. Since the

1970s, electronic FHR monitoring has emerged as the most common technology to monitor fetuses during labor, in the hopes of identifying at-risk fetuses to effect delivery before permanent harm is done. This technology has been successful in largely eliminating intrapartum fetal death. It has likely resulted in a dramatic increase in unnecessary cesarean deliveries, however, without reducing the rate of cerebral palsy. It is hoped that future research and technology development will refine and improve this technology and result in benefit to mothers and infants.

CHAPTER 11

Surgical Treatment of the Fetus

Timothy M. Crombleholme and Foong-Yen Lim

Prenatal diagnosis has become increasingly sophisticated, and technological advances have enhanced not only our range of diagnostic capabilities but our understanding of prenatal natural history as well. Invasive therapies have developed as a natural consequence of our expanded understanding of the natural history and pathophysiology of structural anomalies.[7,70] In the 1960s and 1970s, despite rapid progress in prenatal diagnosis, few invasive therapies were considered, much less employed.[1] Once a diagnosis was made prenatally, parents had only two alternatives: pregnancy termination, if the diagnosis was made before 24 weeks of gestation, or continuing to term.[96] An additional option is altering the site of delivery so that the appropriate pediatric specialists would be available immediately to treat the newborn with a congenital anomaly. As the natural history of many prenatally diagnosed anomalies became better understood, early delivery was recognized as an option to avoid the continuing damage caused by the anomaly in utero.[5,7] Today there are more alternatives. This chapter describes the treatment options available, how they were developed (Table 11-1), and new therapies that may be available in the future.

FETAL SHUNTING PROCEDURES

A new era in invasive fetal therapy began in the early 1980s, when several independent groups introduced shunting procedures for hydrocephalus and hydronephrosis.[30,66,78] These first few cases represented an extension of invasive fetal therapy from simple intrauterine blood transfusion for a medical illness to the first attempts at in utero treatment of structural anomalies (Table 11-2).

During this period, hydronephrosis and hydrocephalus were being recognized more frequently with ultrasound examination. The prenatal natural history of these lesions was established by serial sonographic observation of untreated cases.* Fetuses with high-grade obstructive uropathy followed to term were often born with advanced hydronephrosis, type IV cystic dysplasia, and pulmonary hypoplasia that were incompatible with life.[23,45,167] In the case of obstructive hydrocephalus, it was known that shunting during the newborn period improved neurologic outcome, and it was reasoned that decompression in utero might avert progressive brain damage.[131,137,208] However, the poor outcomes observed with shunting for hydrocephalus resulted in a moratorium on the use of shunts in the treatment of obstructive hydrocephalus.[29] In other conditions, work by numerous investigators using appropriate animal models helped define the pathophysiology of these lesions and establish the theoretical basis for intervention.[6,74-76,86,87]

Hydronephrosis

The first case of a fetus with obstructive uropathy treated in utero by vesicoamniotic shunting was reported by Golbus and colleagues in 1982.[78] Advances soon followed in diagnosis, technique, shunt design, and patient selection.† The enthusiasm for treating fetal obstructive uropathy has continued unabated during the past two decades. The procedure became widely implemented before stringent selection criteria for treatment were developed and the therapeutic efficacy of the procedure was established. The widespread use of vesicoamniotic shunts also had the effects of shifting cases away from the centers where these questions were being studied and limiting attempts to better define the role of vesicoamniotic shunting in the management of fetal obstructive uropathy.

The lack of a prospective, randomized trial makes the efficacy of prenatal decompression the most difficult question to address in the treatment of fetal obstructive uropathy. One of the few series that attempted to address this question, albeit in a retrospective analysis, was reported by Crombleholme

TABLE 11–1 Treatable Fetal Malformations

Fetal Malformation	Fetal Presentation	Fetal/Neonatal Consequences	Fetal Treatment Options
Acardiac/acephalic twin (TRAP sequence)	Polyhydramnios	IUFD, hydrops, cardiac failure Multifocal leukoencephalomalacia	Fetoscopic cord ligation Fetoscopic cord coagulation
Amniotic band syndrome	Edematous limb from constricting band	Limb amputation	Fetoscopic laser lysis of bands
	Umbilical cord constriction	Fetal death	—
Aqueductal stenosis	Rapidly progressive isolated hydrocephalus	Neurologic damage	Ventriculoamniotic shunt Ventriculoperitoneal shunt
Complete heart block	Hydrops, slow heart rate	IUFD, neonatal death	Fetal epicardial pacemaker
Congenital diaphragmatic hernia (CDH)	Herniated viscera in chest	IUFD, pulmonary hypoplasia and respiratory insufficiency, neonatal death	Open fetal tracheal clip Fetoscopic tracheal clip Fetoscopic tracheal balloon
Cystic adenomatoid malformation of the lung (CCAM)	Chest mass, mediastinal shift Hydrops	Pulmonary hypoplasia, IUFD, neonatal death	Thoracoamniotic shunt (if there is dominant cyst) Fetal resection of CCAM (if it is solid tumor)
Fetal hydrothorax	Mediastinal shift, hydrops, polyhydramnios	Pulmonary hypoplasia	Thoracoamniotic shunt
Myelomeningocele (MMC)	Neural tube defect, “lemon” sign, “banana” sign	Paralysis, hindbrain herniation Hydrocephalus	Open fetal MMC repair
Neck masses (cervical teratoma, lymphangioma)	Polyhydramnios, neck mass, absent stomach bubble	Inability to ventilate due to lack of airway Anoxic brain injury, neonatal death	EXIT procedure
Ovarian cyst	Wandering cystic abdominal mass	Ovarian torsion, polyhydramnios	Cyst aspiration
Posterior urethral valves	Hydronephrosis and oligohydramnios	Renal dysplasia and renal insufficiency Pulmonary hypoplasia and respiratory insufficiency	Vesicoamniotic shunt Cystoscopic laser ablation of valves Open vesicostomy
Sacrococcygeal teratoma	High output failure Hydrops	IUFD, prematurity, tumor rupture, hydrops, hemorrhage	Open resection Radiofrequency coagulation
Twin-twin transfusion syndrome	Oligohydramnios and polyhydramnios, growth discordance	IUFD, heart failure Multifocal leukoencephalomalacia	Serial amnioreduction Microseptostomy Cord coagulation Selective laser photocoagulation

EXIT, ex utero intrapartum treatment; IUFD, intrauterine fetal death; TRAP, twin reversed arterial perfusion

and coworkers.[38] In fetuses predicted to have either good or poor prognoses by fetal urine electrolyte and ultrasound criteria, survival was greater among those who underwent decompression in utero, as opposed to those who did not undergo decompression. In the group of fetuses predicted to have a poor prognosis by selection criteria, 10 were treated. Three of these pregnancies were electively terminated, four neonates died of pulmonary hypoplasia or renal dysplasia, and three survived. All three survivors had restoration of normal amniotic fluid (AF) levels and no pulmonary complications, but in two of the three, renal failure subsequently developed and the patients underwent renal transplantation. Among the 14 patients with no intervention, there were no survivors (11 terminations and three neonatal deaths from pulmonary hypoplasia). In the entire series, uncorrected oligohydramnios was associated with a 100% neonatal mortality rate. Normal or restored amniotic fluid volume was associated with a 94% survival rate.[38]

Although in utero decompression seems to prevent neonatal death from pulmonary hypoplasia, the effect on renal function is less clear. The severity of renal dysplasia at birth depends on the timing and severity of obstruction before birth.* Experimental work suggests that relief of obstruction

Ovarian cyst	Wandering cystic abdominal mass, polyhydramnios	Ovarian torsion

during the most active phase of nephrogenesis (20 to 30 weeks of gestation) may obviate further damage and allow normal nephrogenesis to proceed.* The development of postnatal renal failure in two infants who were not treated because amniotic fluid volume remained normal raises the question of whether to treat fetuses with obstruction before oligohydramnios develops. Because renal development or maldevelopment is complete at birth, relief of obstruction in infancy or childhood may not prevent the progression to end-stage renal failure.[199] Müller and associates reported on a group of fetuses with obstructive uropathy, a favorable prognostic profile, and normal amniotic fluid, in whom renal insufficiency developed by 1 year of age.[155] The only feature that distinguished this group of fetuses was a urinary level of β_2-microglobulin greater than 2 mg/L. Elevated fetal urinary levels of β_2-microglobulin may identify fetuses at increased risk for ongoing renal damage from obstruction, even when amniotic fluid is normal. Other investigators have not found β_2-microglobulin levels to be as useful, and levels greater than 10 mg/L can be a predictor of poor outcome in fetuses older than 20 weeks' gestation.[65] It remains an open question whether in utero decompression could prevent long-term renal insufficiency in these patients.

The maternal morbidity associated with vesicoamniotic shunting has been reported to be minimal, but chorioamnionitis related to the procedure has been reported.[38,77] In addition, there have been reports of shunt-induced abdominal wall defects with herniation of bowel through trochar stab wounds and maternal ascites from leakage of amniotic fluid through the uterine wall into the maternal peritoneal cavity.[143,176,178]

The utility of vesicoamniotic shunts is limited by the brief duration of decompression, the risk of infection, the risk of catheter obstruction or dislodgment, fetal injury during placement, and potentially inadequate decompression of the fetal urinary tract.[36,38,61,77] These factors make vesicoamniotic shunts less effective in long-term decompression of the urinary tract early in gestation and are the impetus for development of open fetal surgical and fetoscopic techniques to treat obstructive uropathy in utero.[36,40,61]

Fetal Hydrothorax

Thoracentesis is a diagnostic maneuver done to obtain pleural fluid for differential cell count and culture and to establish whether the effusion is chylous (Fig. 11-1). But even repeated thoracenteses provide inadequate decompression of the fetal chest. There have been several reports of thoracentesis for fetal hydrothorax that have resulted in either complete resolution or a good outcome despite reaccumulation.[12,127,164] However, other results of repeated thoracentesis for fetal hydrothorax have been disappointing because of rapid reaccumulation of the effusion and neonatal death resulting from respiratory insufficiency.[135,159] Spontaneous resolution of fetal

Figure 11–1. hydrothorax may occur in as many as 10% of cases, and resolution following thoracentesis may or may not be related to the procedure. Thoracentesis alone cannot adequately decompress the fetal chest to allow pulmonary expansion and prevent pulmonary hypoplasia.[129]

Thoracoamniotic shunting for fetal hydrothorax, first reported by Rodeck and colleagues in 1988, provides continuous decompression of the fetal chest, allowing lung expansion.[175] If instituted early enough, this allows compensatory lung growth and prevents neonatal death resulting from pulmonary hypoplasia. Nicolaides and Colleagues reported on 48 cases of thoracoamniotic shunting, but there was no attempt to distinguish isolated primary fetal hydrothorax from secondary fetal hydrothorax.[159] Despite intervention, mortality was high. Four deaths were due to termination of pregnancy when a chromosomal abnormality was diagnosed. In addition, there were 12 neonatal deaths despite thoracoamniotic shunt placement, but these fetuses seemed to have severe hydrops and secondary fetal hydrothorax. Two fetuses that died in utero also seemed to have had secondary fetal hydrothorax and severe hydrops. If the cases that appear to be secondary fetal hydrothorax are eliminated, the survival of isolated primary fetal hydrothorax treated with thoracoamniotic shunting is 38 of 41 (92%) cases.[153,159] A similar survival rate with thoracoamniotic shunting was found by Hagay and coworkers in their review of fetal pleural effusions.[83] This is a striking improvement when compared with a survival of only 50% in untreated fetal hydrothorax.

The indications for thoracoamniotic shunting are not well defined. Most authors consider the presence of fetal hydrothorax-induced hydrops or polyhydramnios as indications for shunting (Fig. 11-2).[135,159,175] We recommend thoracoamniotic shunting for primary fetal hydrothorax with evidence of effusion under tension even in the absence of hydrops.[153] Because spontaneous resolution has been observed even in severe cases of fetal hydrothorax, we reserve thoracoamniotic shunting for cases in which tension hydrothorax recurs after two thoracenteses. The two currently available catheters are the Harrison double-pigtail catheter (VPI Company, Spenser, IN) and the KCH catheter (Rocket USA Inc., Branford, CN) (Fig. 11-3).

The limited experience with thoracoamniotic shunting suggests that it is extremely effective in decompressing effusion and improving survival. The risks to mother and fetus of thoracentesis and shunt placement have been minimal and are far outweighed by the potential benefits. Few complications have been reported for either fetal thoracentesis or thoracoamniotic shunts. Procedure-related fetal death is rare, due to hemorrhage from an intercostal artery laceration or torsion of the umbilical cord.[135] Migration of the shunt under

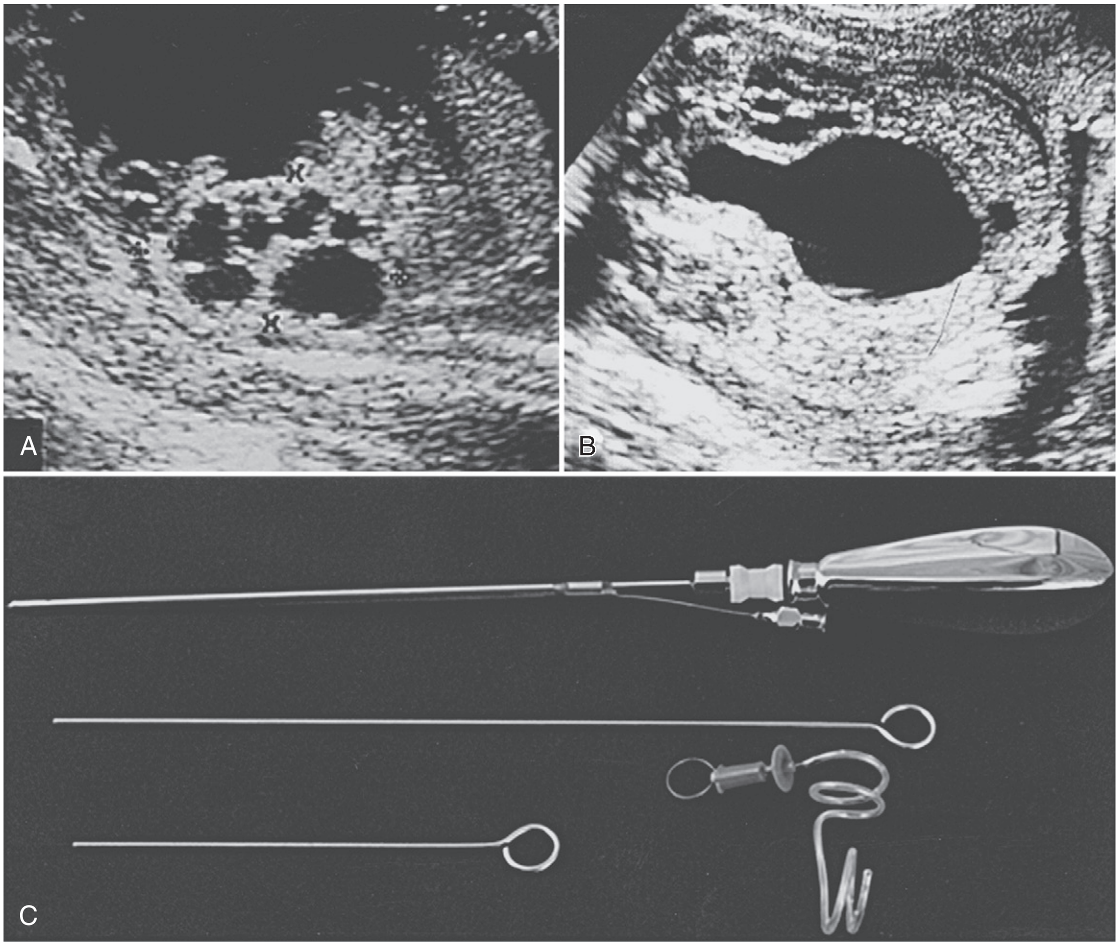

Figure 11–3. **A**, Fetal sonogram demonstrating hydronephrosis with caliceal dilation owing to posterior urethral valves. **B**, Obstructed bladder outlet demonstrating the "keyhole" sign owing to posterior urethral valves. **C**, Standard trocar and Rocket catheter for fetal shunting procedures. *(From Shaaban AF et al: The role of ultrasonography in fetal surgery and invasive fetal procedures,* Semin Roentgenol *34:62, 1999.)*

the fetal skin has also been reported, but required no intervention when the infant was born.[175] No maternal complications have been reported with either thoracentesis or thoracoamniotic shunting. However, these procedures do have the potential for significant complications, including infection, bleeding, premature rupture of membranes, preterm labor, and injury to the fetus.[153]

There are currently two devices approved by the Food and Drug Administration (FDA) that are available for shunt placement in a broad range of applications, including bladder outlet obstruction, pleural effusions, and cyst decompressions in congenital cystic adenomatoid malformation. The Harrison catheter (Cook Inc., IN) is available in a complete shunt insertion kit that includes not only the polyurethane shunt but also the trocar for insertion, the guidewire over which the double pigtail catheter is threaded, and the pusher that deploys the shunt. The advantages of the Harrison catheter include the ease of insertion and the complete kit it comes with. The disadvantage of the Harrison catheter is that it is more easily dislodged.

The alternative catheter is the Rocket or KCH catheter (see Fig. 11-3C). The Rocket catheter requires a reusable trocar insertion device which is larger and somewhat more difficult to use compared to the Harrison catheter set. The advantage of the Rocket catheter is that it is less likely to be dislodged. The larger size of the Rocket trocar may make this less appealing for chest shunt insertion due increased difficulty inserting the shunt and increased risk of laceration of the intercostal artery, especially in fetuses at less than 25 weeks' gestation.

Miscellaneous Procedures and Other Indications for Shunts

Small ovarian cysts are common in neonates. They are typically small follicular cysts due to maternal hormonal stimulation and are rarely clinically significant. They usually regress spontaneously.[121] The prenatal diagnosis of an ovarian cyst should be considered in any female fetus with a cystic pelvic mass. Although they can be mistaken for mesenteric cysts, duplications, urachal cysts, or choledochal cysts, ovarian cysts are usually simple pelvic cysts that disappear shortly after delivery. Occasionally, these cysts require surgery for complications due to size, rupture, or torsion.[121,128] Once an ovarian cyst becomes symptomatic, salvage of the ovary is unlikely.

Valenti and coworkers were the first to perform cyst decompression in utero, in 1975.[196] A large (7 by 9 cm) ovarian cyst was aspirated to prevent intrapartum cyst rupture. Landrum and associates reported fetal ovarian cyst aspiration ostensibly to prevent pulmonary hypoplasia.[130] Whereas pulmonary hypoplasia from a pelvic mass is unlikely, aspiration to prevent in utero rupture or torsion and to preserve ovarian tissue is a more appropriate indication for treatment. Holzgreve and colleagues have reported their experience with 13 cases of fetal ovarian cysts.[114] This group recommends ovarian cyst decompression to preserve the ovary, especially when the cyst is large, rapidly increasing in size, or observed to be a "wandering mass." Cysts exhibiting these features are more likely to undergo torsion. Cyst tap revealing high levels of prostaglandin F21, progesterone, and testosterone in the fluid confirms the diagnosis. Giorlandino and associates reported a case of ovarian cyst treated by cyst aspiration and sclerosis with tetracycline.[73] Even though this treatment was successful, the use of tetracycline as a sclerosing agent in the fetus is not advised. Giorlandino and associates subsequently reported success in four cases of simple cyst aspiration.[72] Similarly, D'Addario and colleagues aspirated ovarian cysts in two fetuses, but neonatal surgery was still needed.[47] Crombleholme and coworkers have suggested criteria for intervention in fetal ovarian cysts with diameters of more than 4 cm, of fetal ovarian cysts increasing 1 cm per week in size, or (as Holzgreve suggested) of cysts noted to wander about the abdomen.[39] Although fetal ovarian cyst decompression seems a relatively benign procedure with the potential for ovarian preservation, the indications for fetal intervention are not uniformly accepted.

In 1987, Nicolaides and coworkers reported the first case of cystic adenomatoid malformation of the lung (CCAM) treated by shunt insertion in utero.[158] Decompression of a large type I CCAM in a 20-week-old fetus by percutaneous placement of a thoracoamniotic shunt was subsequently reported by Clark and associates in 1987.[28] This procedure resulted in resolution of both mediastinal shift and hydrops and successful delivery at 37 weeks of gestation. Postnatally, the infant underwent uneventful resection of the CCAM. Recently, Wilson and associates reviewed the Children's Hospital of Philadelphia (CHOP) experience with thoracoamniotic shunts for cystic CCAMs demonstrating an average acute 70% reduction in CCAM volume with a 74% survival with thoracoamniotic shunting in the presence of hydrops, polyhydramnios, or fetuses at increased risk for development of pulmonary hypoplasia.[204] This experience is consistent with other reports of CCAMs with a dominant cyst that responded to thoracoamniotic shunt placement.[2,204,206] There are, however, potential procedure-related complications, including catheter dislodgment, catheter occlusion from thrombus, fetal hemorrhage, placental abruption, premature rupture of membranes or preterm delivery, and chest wall deformity.[57,142,150] More commonly, it is the type III CCAM, or microcystic lesions, which become enlarged, resulting in hydrops and intrauterine fetal death. In these latter cases open fetal surgery and resection are indicated. However, in the rare instances in which there is a single large cyst in CCAM responsible for hydrops, thoracoamniotic shunting appears to be an appropriate treatment option.

FETAL CARDIAC PROCEDURES

Fetal Arrhythmias

Fetal arrhythmias are most often ventricular extrasystoles or tachyarrhythmias. But bradyarrhythmias account for 9% of cases reported to the Fetal Arrhythmia Registry, half of which occur in structurally normal hearts due to transplacental passage of antibody in mothers with collagen vascular disease.[123] The other half occur in structurally abnormal hearts, and bradyarrhythmia is almost uniformly fatal in that setting.[122,189] In structurally normal hearts in which complete heart block develops in mothers with collagen vascular disease, hydrops develops in 25% and is usually refractory to medical therapy.[9,21,139] Based on the combined retrospective experience from researchers in Toronto and at the University of California at San Francisco (UCSF), fetuses with complete heart block may benefit from the combination of maternal steroids and β-mimetics. There is no expectation that steroids will improve the fetal heart rate but may reduce maternal Ab titer and transplacental passage and limit the ongoing injury to the fetal cardiac conduction system and the myocardium. If low-output fetal heart failure cannot be reversed by increasing heart rate with β-agonists, then fetal cardiac pacing is the only alternative. Carpenter and colleagues reported the first fetus treated by implantation of a percutaneous transthoracic pacemaker.[21] Unfortunately, the fetus was severely hydropic and despite successful ventricular capture and pacing, the fetus died within hours. The obvious problems with the percutaneous transthoracic pacemaker are the risks of dislodgment, potential for infection (chorioamnionitis), and the temporary nature of the device in a fetus that will require pacing for the rest of gestation. These limitations prompted a group led by Michael Harrison at UCSF to attempt pacemaker placement by open fetal surgery.[89] Previous work by Crombleholme and coworkers had developed the techniques for acute and chronic fetal cardiac pacing and studied the effects of complete heart block in fetal lambs.[33,35] Based on this experimental work, Harrison and coworkers placed a unipolar epicardial pacemaker in a fetus at 22 weeks of gestation with complete heart block and hydrops.[89] Similar to Carpenter and colleagues' experience, although able to achieve ventricular capture and pacing, the heart was irreversibly damaged by 6 weeks of in utero cardiac failure and the procedure resulted in fetal death in the operating room.[21,89] More recently, Crombleholme and coworkers performed open fetal surgery for placement of epicardial pacing lead with an implantable programmable pulse generator in VVI mode.[41] The pacemaker was set at 65 beats per minute which doubled the combined ventricular output measured by echocardiography. The fetus expired on postoperative day 5 and autopsy found extensive renal and hepatic ischemic injury that likely preceded the fetal surgery.[41] It is clear from these reports that a fetus with longstanding complete heart block with severe hydrops may already have significant end organ injury, which may be unsalvageable despite successful pacemaker placement. The survival of fetuses with complete heart block and ventricular escape rates of less than 50 beats per minute is poor.[184] Placement of a pacemaker in the fetus with a ventricular response rate of less than 50 beats per minute before the development of hydrops may allow salvage of these otherwise doomed fetuses.

Structural Fetal Heart Disease

Structural cardiac defects, such as pulmonic atresia with an intact ventricular septum (PAIVS) or severe aortic stenosis, may result in obstruction to blood flow, which in turn alters the development of the heart chambers as well as the pulmonic and systemic vasculature in utero.[198] The major morbidity from these congenital heart defects often results from the secondary alterations in heart development caused by the primary defect (i.e., hypoplasia of the right ventricle in PAIVS or hypoplastic left heart syndrome [HLHS] in aortic stenosis). In theory, relief of the anatomic obstruction in utero may allow more normal cardiac development, thereby eliminating the need for corrective surgery postnatally.

Aortic stenosis diagnosed prenatally is associated with intrauterine fetal death or neonatal death in fetuses that survive to term. Maxwell and associates reported a series of 28 fetuses diagnosed prenatally with aortic stenosis either alone or associated with endocardial fibroblastosis.[147] Only 12 mothers continued the pregnancy to term, and in two there was an intrauterine fetal death. None of the 10 neonates survived despite balloon valvuloplasty in four of them. Maxwell and coworkers also noted that in four fetuses, the left ventricle failed to grow, resulting in hypoplastic left heart, which would make the neonate unsuitable for postnatal aortic valve reconstruction.[147] This grim natural history for fetuses with prenatally detected aortic stenosis, as well as poor outcomes with the Norwood procedure in their institution, prompted Maxwell and colleagues to attempt the first in utero aortic balloon valvuloplasty.[147] This procedure was performed by direct percutaneous puncture of the left ventricle under ultrasound guidance. A J wire is passed through the stenotic valve, and the balloon catheter is passed over the wire and inflated. All three fetuses treated with this procedure survived to term; two died as neonates and one was doing well to a follow-up of 3 years of age.[147] Two other fetuses were treated unsuccessfully by this technique by Chouri and colleagues.[27]

More recently, the group at Boston Children's Hospital has reintroduced fetal balloon valvuloplasty in an effort to prevent progression of aortic stenosis to hypoplastic left heart syndrome (HLHS).[140] In their initial experience with 43 fetuses with diagnosed aortic stenosis, the researchers retrospectively identified a subset of patients that all progressed to HLHS postnatally. These fetuses all had aortic stenosis associated with normal left ventricular length, reversed flow in the transverse aortic arch or foramen ovale, and a monophasic mitral inflow pattern. Several centers soon followed with reports of attempts at fetal aortic valvuloplasty. Although most centers' experience is quite small, there appears to be a steep learning curve judging from the largest series reported thus far.[146,195] "Technical success," defined as increased flow across the aortic valve, has been achieved in 75% of cases but it is unclear how often a technically successful procedure achieves an eventual biventricular circulation postnatally.[146] This contrast between technical success and postnatal success suggests that current selection criteria do not accurately select fetuses that are likely to respond to balloon valvuloplasty.

Wright and associates have performed radiofrequency pulmonic valvotomy in a fetus with pulmonary atresia with intact ventricular septum (PAIVS).[207] In the most severe forms of PAIVS, the primary valvular lesion causes secondary alteration in the intracardiac flow pattern, resulting in a hypoplastic right ventricle.[22] In these instances, only palliative pulmonary valvotomy and systemic-to-pulmonary artery shunting can be performed. However, if flow can be reestablished across the pulmonic valve in utero, restoration of intracardiac blood flow may allow subsequent growth of the right ventricle and pulmonary outflow tract. The indications for fetal balloon valvuloplasty in PAIVS include a cardiovascular profile score of less than 7, decreased biventricular cardiac output, severe pulmonary stenosis, possible elevated right ventricular pressure, and possible hydrops.[146] In a 26-week-old fetus with PAIVS, no growth was observed in the right ventricle during 6 weeks of in utero observation. By direct puncture of the right ventricle, a pulmonary valvotomy was performed using a radiofrequency ablation catheter. Although only a minute hole with insignificant flow resulted, this procedure and those reported by Maxwell and colleagues and by Chouri and colleagues have established the feasibility of in utero treatment of structural heart disease. Although there have been technical successes, the outcomes have not been different from the natural history of PAIVS due to growth failure of the pulmonic valve annulus.[69,146]

These procedures are certainly not without risk. One of Maxwell's patients died within hours of the procedure and pieces of balloon and guidewire were left within the fetal heart. All three centers noted pericardial effusions that needed to be evacuated at the conclusion of the procedure. In the series reported by Marshall and coworkers, in 20 of 26 patients with technically successful procedures, 12 had at least mild pulmonary valve regurgitation at the procedure.[145] In a report from the same group, in a series of 83 fetuses, 45% (37 fetuses) experienced fetal hemodynamic instability associated with transventricular approach and the development of large hemopericardium.[149] In 31 of the 37, resuscitation medications were used and in all 37 the hemodynamic stability was restored. However, there were five fetal deaths (5 of 63, 8%) within 24 hours of the procedure.[149] Despite the risk of these procedures, the unfavorable outcomes for the fetuses with these structural heart defects argues in favor of continued efforts at developing safe and effective invasive fetal therapies.

FETSOSCOPIC SURGERY

Diagnostic Fetoscopy

Embryoscopy was first performed via the transcervical approach early in gestation, before fusion of the chorion and amnion, to make a phenotypic diagnosis.* Percutaneous techniques were then developed to introduce the fetoscope directly into the amniotic cavity transabdominally. Many of the initial indications for fetoscopic guidance are procedures that now are routinely performed with ultrasound guidance alone. In some instances, however, diagnostic fetoscopy can still be a useful adjunct to ultrasound, especially early in gestation. The suspicion of a significant fetal anomaly earlier than 14 weeks' gestation may be difficult to definitively resolve with ultrasound alone and is too early in gestation for magnetic resonance imaging (MRI).[52]

*References 46, 58, 59, 68, 71, 180, 202.

Duchenne muscular dystrophy (DMD), a progressive, degenerative muscle disease, is inherited as an X-linked recessive trait. It is one of the more common genetic diseases among all populations, affecting approximately one in 3500 live-born male infants. DMD is caused by the deficiency of a protein component of muscle tissue called *dystrophin*. Dystrophin is part of the membrane cytoskeleton in normal muscle, and a deficiency leads to myofiber necrosis, presumably because of membrane instability. Whereas 70% of cases are inherited through a carrier mother, approximately 30% of cases occur without previous family history, representing apparent de novo mutations in the dystrophin gene.[154] Because of isolation of the dystrophin gene and its normal protein product, diagnosis of this disorder can now be made on a molecular basis.[111,124] However, because of the tremendous size of the DMD gene and variation in molecular abnormalities, the underlying gene defect (usually a deletion) is identified in only 65% of affected individuals. In such a case, however, female carriers can be identified with molecular testing and future male pregnancies can be tested for that specific familial gene defect.

In 1991, the first case of in utero fetal muscle biopsy for DMD diagnosis was described in a family in which the carrier status of the mother could not be determined.[62] Using a renal biopsy device directed into the fetal buttock by high-resolution ultrasound guidance, a satisfactory biopsy of skeletal muscle was obtained for analysis and was subsequently shown to contain normal amounts of the dystrophin protein. DMD and other genetic conditions remain a rare but important indication for fetoscopically guided biopsy.

Therapeutic Fetoscopy

LOWER URINARY TRACT OBSTRUCTION (see Chapter 51)

Fetal lower urinary tract obstruction can result in progressive oligohydramnios, pulmonary hypoplasia, and cystic renal dysplasia. Occurring mostly in males, common etiologies include posterior urethral valves, urethral atresia, and urethral hypoplasia. The presence of significant bladder dilation, bilateral hydronephrosis, and severe oligohydramnios before 20 weeks' gestation is almost universally associated with in utero or early neonatal death if left untreated. Experimental models of ureteral obstruction in sheep suggest that early reversal of obstruction in midgestation can prevent progression of renal damage and potentially improve postnatal survival and renal outcomes.[75] This work led to the concept of in utero therapy either by open fetal surgery or vesicoamniotic diverting shunts that drain urine from the bladder to the amniotic space.[36, 92,96]

However, shunt placement is a technically challenging, invasive procedure, and long-term shunt success is variable, largely due to shunt obstruction or displacement. Functional shunt failure has been reported to occur in 40% to 50% of cases after successful placement, mostly due to displacement of the shunt into the fetal abdomen or amniotic space.[101] Because of the displacement issue and the bladder dysfunction that results after catheter decompression, alternative approaches such as fetal cystoscopy have been attempted.

One approach has been based on postnatal therapy for such disorders that involves cystoscopic identification of the underlying etiology, and in cases of posterior urethral valves, destruction of the membranous obstruction. However, developing such an approach in an 18- to 20-week fetus has proven problematic. Engineering and manufacturing advances have produced successive generations of smaller fiberoptic endoscopes that have made the possibility of fetal cystoscopy a reality. Initially, using a variety of 1.7- to 2.2-mm endoscopes, Quintero and colleagues were able to show that in utero diagnostic fetal cystoscopy was possible and later were able to identify proximal urethral obstructions.[168] Several attempts at laser ablation of posterior urethral valves were technical successes, but postoperative obstetric complications resulted in no long-term survivors from this early experience.[170] Using a 1.2- × 2.4-mm double-lumen trocar sheath, it is possible to pass wire probes or laser fibers to assist in diagnostic evaluation and offer the possibility of laser ablation of posterior urethral valves. Design modifications and refinements to this system have recently allowed fetoscopists to more reliably visualize the source of proximal urethral obstruction and differentiate between urethral atresia and posterior urethral valves. Visualization of the posterior urethral valves may be difficult at gestational ages greater than 20 weeks due to increased angulation at the posterior urethra. Clifton and coworkers have added the placement of a transurethral stent to disrupt the valves with good renal function and bladder function at one year postnatally.[32] It is hoped that by treating the source of the obstruction in midgestation, renal function will be preserved and the need for postnatal urologic surgery to correct secondary anatomic abnormalities may be eliminated. However, despite a compelling rationale for fetal cystoscopic treatment of posterior urethral valves and advances in fetoscopic techniques, this approach has yet to be shown to be a more effective treatment of lower urinary tract obstruction than vesicoamniotic shunting. The limitations and poor outcomes of shunting procedures and fetoscopic approaches to treating bladder outlet obstruction have renewed interest in open fetal surgery for vesicostomy.

DIAPHRAGMATIC HERNIA (see Chapter 44)

Congenital diaphragmatic hernia (CDH) is a simple anatomic defect in the diaphragm, but in severe cases it may result in profound pulmonary hypoplasia precluding postnatal survival.[84,85] This prenatal natural history of CDH has led to attempts to correct the diaphragmatic defect before birth, with some anecdotal success. It had been recognized in the physiology literature for decades that occlusion of the fetal trachea results in accelerated lung growth.[8,20] This technique was applied in animal models of CDH, demonstrating that tracheal occlusion can correct the pulmonary hypoplasia associated with CDH.[56,107] This work was quickly replicated in other laboratories and was pioneered in clinical application by Harrison and the University of California at San Francisco (UCSF) group using open fetal surgical techniques to occlude the trachea.[90] The survival using an open fetal surgical approach, however, was disappointing, and fetoscopic techniques of tracheal occlusion were developed in hopes of avoiding the problems of preterm labor and complications from tocolytic agents associated with hysterotomy.[4,64,98] The fetoscopic techniques used for tracheal occlusion have evolved with growing experience by the UCSF and Eurofetus group.

In their initial approach with the "Fetendo" clip, Harrison and colleagues reported a 75% survival rate compared with 15% in the open fetal surgical approach to tracheal occlusion and a 38% survival rate with standard postnatal therapy.[88] Not only did survival appear to be improved in this small series, but there was also a trend toward less preterm labor, less need for tocolysis, and a shorter hospital stay. The UCSF group further refined their technique, eliminating the multiple ports and the neck dissection entirely by performing an endoluminal balloon tracheal occlusion.[94] A single port is used to introduce a fetoscope into the amnion and the fetal oropharynx. The vocal cords are fetoscopically viewed for passage of a detachable balloon catheter through the vocal cords. The position in the trachea is determined sonographically before inflation and deployment of the balloon. This technique was piloted in several cases of right-sided CDH and is being evaluated in a National Institutes of Health (NIH)-sponsored prospective, randomized clinical trial comparing fetoscopic endoluminal balloon tracheal occlusion with conventional postnatal therapy.

The NIH trial of fetoscopic tracheal occlusion was halted after randomization of only 24 subjects when it became apparent that there would be no significant difference in survival between the fetoscopic tracheal occlusion group and the conventional therapy group. The fetoscopic surgery group had a 73% (8 of 11) survival rate, as predicted by preliminary data, but the conventional postnatal treatment group had a better than predicted survival rate of 77% (10 of 13). The fetoscopically treated patients delivered significantly earlier compared with conventional treatment at a mean of 30.8 versus 37 weeks, respectively. The entry criteria for this study was lung-to-head ratio less than 1.4, which resulted in a number of patients being included that would be expected to do well with conventional postnatal therapy. European centers that are a part of the Eurofetus FETO (Fetoscopic Endoluminal Tracheal Occlusion)—in Leuven, Belgium; Barcelona, Spain; London, United Kingdom—have collaborated on fetoscopic tracheal occlusion for lung-to-head ratio less than 1 with liver herniation. This has resulted in a survival rate of 55%, which compared favorably with conventional postnatal therapy in their neonatal centers with 11% survival.[53] More recently, Deprest and coworkers reported survival rate of 93% with fetoscopic tracheal occlusion and reversal later in gestation.[53] The reversal of tracheal occlusion is performed by either a second fetoscopic procedure for removal or by ultrasound-guided balloon puncture. The detachable balloon used in tracheal occlusion in Europe is not FDA approved in the United States. Centers in the United States, including UCSF and the Fetal Care Center of Cincinnati, are obtaining investigational device exemptions (IDEs) to perform fetoscopic tracheal occlusion in severe CDH, liver up, and lung-to-head ratio less than 1 between 26 and 28 weeks' gestation (Fig. 11-4).

Attempts at treating fetal sacrococcygeal teratoma with minimally invasive fetoscopic techniques have met with mixed results. Hecher and colleagues reported the successful

treatment of a sacrococcygeal teratoma by fetoscopy using laser.[104] The base of this sacrococcygeal teratoma was unusually narrow, without distortion of the anorectal sphincter complex onto the mass. This is an important consideration, in that most fetal sacrococcygeal teratomas distort the anorectal sphincter complex, and such a fetoscopic approach as described by Hecher might result in ischemic necrosis of the anorectal sphincter complex along with the sacrococcygeal teratoma. In addition, the superficial vessels are the only ones accessible to the laser, whereas the deeper pelvic vessels, which may be more important in the development of high-output physiology, are inaccessible. These difficulties are highlighted by the UCSF experience with the use of radiofrequency ablation.[161] The goal was the coagulation of the feeding vessels to the sacrococcygeal teratoma that are responsible for the high-output state. The power of the radiofrequency ablation in this ultrasound-guided technique could not be precisely controlled and the fetus sustained necrosis of the anus, vagina, and bladder, with injury to the sciatic nerve.[161]

MYELOMENINGOCELE (see chapter 40)

In recent years, fetal surgery has moved from the treatment exclusively of life-threatening fetal anomalies such as congenital diaphragmatic hernia, sacrococcygeal teratoma, or hydropic CCAMs to fetal anomalies that are severely debilitating, but not life-threatening. Myelomeningocele may be the most controversial of the current nonlethal indications for fetal surgery. Even though fetal repair of myelomeningocele is now performed using open fetal surgical techniques, it was first attempted using a fetoscopic approach by the group at Vanderbilt.[17,18] The maternal uterus was exteriorized and three fetoscopic ports were placed, one for the fetoscope and two operative ports.[18] A maternal split-thickness skin graft was placed over the myelomeningocele defect and secured using Surgicel and fibrin glue in four patients between 22 and 24 weeks' gestation. The maternal results were disappointing: two fetal losses occurred, one from intrauterine fetal demise due to placental abruption and the other due to severe prematurity. Although the intent was palliative (i.e., providing cover and protection to the neural tube defect in utero to preserve neurologic function until a more definitive repair could be performed postnatally), none of the split-thickness skin grafts survived. The two survivors in this small series did not appear to benefit from this procedure, and the Vanderbilt group has abandoned this approach in favor of an open surgical technique until technical advances in fetoscopic instrumentation possibly make this a viable alternative approach.[194] More recently, Kohl and colleagues reported fetoscopic closure using a Gore-Tex patch in myelomeningocele to protect the exposed spinal cord.[125] It is not clear whether the approach offers any advantages over open techniques or the previously reported fetoscopic approach.

AMNIOTIC BAND SYNDROME

The amniotic band syndrome (ABS) is another example of a usually nonlethal anomaly potentially treatable by fetoscopic surgery. ABS is a group of sporadic congenital anomalies (including the ABS limbs, craniofacial regions, and trunk) ranging from constrictive bands to pseudosyndactyly to amputation, as well as multiple craniofacial, visceral, and body wall defects.* Because there are numerous forms of the syndrome, ABS has numerous sonographic features, and these features may occur as isolated problems or in combination. The earliest that amniotic bands have been diagnosed is 12 weeks by endovaginal probe. The bands can be difficult to detect sonographically, and ABS is more often diagnosed by the effect the bands have on fetal anatomy. The effect of amniotic bands on the extremities may be manifested by absent digits or portions of limbs, or a swollen distal arm or leg secondary to constrictive bands. Constrictive bands most commonly affect the extremities but can also involve the umbilical cord, with resulting fetal demise. Kanayama and associates described the reversal of diastolic flow observed in a fetus with umbilical cord constriction due to amniotic bands.[120] Graf and associates similarly reported a case of amniotic bands involving the umbilical cord after the development of chorioamniotic separation.[81] Despite initially normal umbilical artery Doppler waveforms, this fetus died within 2 weeks of a constrictive amniotic band of the umbilical cord. Numerous reports have described constrictive amniotic bands as a cause of fetal demise.[151,191] Recently, Crombleholme and coworkers successfully treated three fetuses with umbilical cord ABS, averting cord accident with survival in all three patients.[43]

We have performed fetoscopic laser release of six cases of extremity amniotic bands, with impending limb amputation. Secondary lymphedema persisted postnatally in two fetuses, while atrophy of the hand occurred in another. One lower extremity in which the band was released before there was irreversible damage was completely normal by the time of delivery. The results of these few cases establish at least the feasibility and safety of performing fetoscopic release of amniotic bands with the potential to salvage the extremities. In cases of umbilical cord involvement, this approach also has the potential for being lifesaving.

Fetoscopic Treatment of Complications in Monochorionic Twins (see chapter 19)

MONOCHORIONIC TWINS DISCORDANT FOR ANOMALY

Twin gestations are at increased risk for the development of congenital anomalies. A range of congenital malformations such as anencephaly, omphalocele, hydrocephalus, and atresia/stenosis of the gastrointestinal tract are more common in twin gestations.[10] Congenital heart defects are twice as prevalent in monozygotic twins than dizygotic twins or singleton pregnancies.[19] In addition, twins that are discordant for anomaly deliver even earlier than the average twin delivery of 34 weeks.[141] Therefore, there are increased risks for the healthy co-twin, not only from intrauterine demise of the anomalous co-twin but also from the risks attendant to extremely premature delivery.

It is important to distinguish the chorionicity of a twin gestation when one of the twins has a structural or karyotypic abnormality. In a dichorionic pregnancy, it is possible to observe spontaneous intrauterine fetal demise or perform selective feticide by means of a potassium chloride injection without significant risk to the healthy co-twin.[79] This is not the case with monochorionic pregnancies in light of the vascular connections between the twins, or chorioangiopagus. In the past, because alternative interventions (e.g., sectio parva or ultrasound-guided embolization) have been unsuccessful, the usual recommendation has been to manage these pregnancies expectantly. In monochorionic gestations, however, this strategy leaves the healthy co-twin at risk for simultaneous intrauterine fetal demise or severe neurologic injury in the event of co-twin demise. Fetoscopic cord ligation or intrafetal radiofrequency ablation provides a viable therapeutic option under these circumstances. Crombleholme and coworkers reported the first use of fetoscopic cord ligation specifically to prevent neurologic injury in a surviving twin when death of a co-twin was anticipated.[42] Several groups have reported success with fetoscopic cord ligation or coagulation in instances in which an anomalous co-twin may threaten the normal twin.[51,117,160] We favor a less invasive approach of ultrasound-guided intrafetal radiofrequency ablation.[133]

TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

Twin reversed arterial perfusion (TRAP) sequence occurs only in the setting of a monochorionic pregnancy and complicates approximately 1% of monochorionic twin gestations, with an incidence of 1 in 35,000 births.[115] In the TRAP sequence, the acardiac/acephalic twin receives all of its blood supply from the normal or so-called “pump” twin. The acardiac twin has a grossly anomalous circulation that is sustained in a parasitic manner by the normal co-twin (“pump” twin) through reversed perfusion of the arterial-arterial anastomoses. Because of the increased demand the abnormal circulation in TRAP sequence places on the heart of the “pump” twin, cardiac failure is the primary concern. If left untreated, the “pump” twin dies in up to 50% to 75% of cases. This is especially true when the acardiac/acephalic twin is more than 50% of the size of the “pump” twin by estimated weight.[152]

At least 33 cases of umbilical cord ligation or coagulation for TRAP sequence have been reported, and an additional seven cases have been treated by umbilical cord laser coagulation.* Laser coagulation is not recommended after 21 weeks’ gestation.[24] The most common complication was the development of premature rupture of membranes, complicating up to 30% of cases.* Challis and associates reported a failure rate for cord coagulation of 10%, with fetal survival of 71% and risk of preterm premature rupture of membranes of 30%.[24]

In recent years, we have converted to the use of intrafetal radiofrequency ablation (RFA) in TRAP sequence with 95% “pump” twin survival. This is consistent with the survival reported by UCSF.[193] The experiences at Cincinnati and UCSF compare favorably with the experience of European groups, an overall survival of 85%, with fetoscopic bipolar electrocautery. Lee and associates reported the North American Fetal Therapy Network (NAFTNet) experience with intrafetal RFA at five centers.[132] Not surprisingly, the centers with the most experience had the best survival and fewest complications.[132]

TWIN-TWIN TRANSFUSION SYNDROME

The natural history of severe twin-twin transfusion syndrome (TTTS) is well established, with mortality approaching 100% when left untreated, especially when TTTS presents at less than 20 weeks’ gestation.[26,182,201]

The first treatment of TTTS that attempted to treat the underlying chorioangiopagus was reported by DeLia and colleagues.[50,197] Fetoscopic laser was used to photocoagulate vessels crossing the intertwin membrane. In the first series of cases of TTTS, DeLia and colleagues reported a survival of 53% in 26 patients.[50] Even though survival was not significantly better than previous reports with serial amnioreduction, the neurologic outcome was normal in 96%. Other groups from Europe have reported similar survival with fetoscopic laser photocoagulation. Ville and coworkers reported 53% survival with a nonselective laser technique, which was better than the survival observed with historical controls at the same center with serial amnioreduction (37%).[197] There also appeared to be an improved neurologic outcome in fetuses treated by laser. Nonselective fetoscopic laser photocoagulation of all vessels crossing the intertwin membrane may be problematic, in that the intertwin membrane often bears no relation to the vascular equator of the placenta. This may result in sacrifice of vessels not responsible for the TTTS, resulting in a higher death rate of the donor twin from acute placental insufficiency.[171] A selective laser photocoagulation technique has been reported.[171] The selective technique does not photocoagulate every vessel crossing the intertwin membrane; only direct, arterial-arterial, and veno-venous connections are photocoagulated, along with any unpaired artery going to a cotyledon with the corresponding vein (and vice versa) going to the opposite umbilical cord (Fig. 11-5). In a nonrandomized comparison of patients treated by serial amnioreduction at one center and selective laser photocoagulation at another, the overall survival was not significantly different (61% for laser versus 51% for serial amnioreduction).[103] However, the survival of at least one twin with laser photocoagulation was 79%, whereas survival of at least one twin with serial amnioreduction was only 60%.[103] This was not a controlled trial, and patients were not randomized.

Quintero and colleagues retrospectively examined data from 78 patients treated by serial amnioreduction and 95 patients treated with selective laser photocoagulation with no significant difference in the distribution of patients by stage.[172] Perinatal survival was not significantly different in the laser versus amnioreduction group (64.2% versus 57.7%). However, there was an inverse relationship between fetal survival and stage in the amniocentesis group but not in the laser group. For stage IV disease, there was a significantly lower fetal survival in the amnioreduction group compared with the laser group (20.6% versus 63.6%, $P = .001$). This information has important implications for evaluation of treatment options and the development of stage-based treatment protocols.

The Eurofoetus trial conducted by Senat and associates was the first prospective, randomized trial that compared the efficacy and safety of treatment of TTTS with laser therapy versus serial amnioreduction.[188] Women presenting between 15 and 26 weeks’ gestation with polyhydramnios in the recipient twin

and oligohydramnios in the donor twin were allowed to participate. Fifty-two percent of patients were stage I or II, 47% were stage III, and 1% were stage IV. Enrollment was halted after a planned interim analysis revealed a significantly higher likelihood of survival of at least one twin to 28 days of age (76% versus 56%, $P = .009$) and to 6 months of age (76% versus 51%, $P = .002$) in the laser group compared with the amnioreduction group. More infants were alive without neurologic abnormalities detected on neuroimaging studies in the laser group as well (52% versus 31%, $P = .003$). The overall survival in the laser arm was 57%. This is consistent with previous reports of nonselective fetoscopic laser (53%).[50] This is significantly lower, however, than the survival reported with selective fetoscopic laser (64% to 68%).[63,102] Of particular concern is the poor survival that was observed in the amnioreduction arm. The overall survival was only 39%, which is significantly lower than previously reported (60% to 65%).[55,60,144,165] Antenatal, peripartum, and neonatal care were provided by the referring hospital and lack of standardization may explain some of these differences.[63] The decreased survival in the amnioreduction group may reflect the higher pregnancy termination rate in the amnioreduction group (16 patients versus 0 patients in the laser group). The terminations were requested after the diagnosis of severe fetal complications; it would be instructive to know whether these women were offered cord coagulation as a means of rescuing one baby.[63] Reliable assessment of neurologic outcome is critical when assessing efficacy of treatment for TTTS. Whereas there was a lower rate of abnormality on neurologic imaging in the laser group (7% versus 17%), long-term neurodevelopmental assessment has revealed no difference in outcome between survivors treated with fetoscopic laser versus those treated with amnioreduction.

The NIH-sponsored TTTS trial is the only other prospective, randomized trial comparing survival with amnioreduction versus selective fetoscopic laser photocoagulation.[34] This trial differed from the Eurofetus trial in several important aspects. First, to qualify for the NIH trial, the TTTS had to fail to respond to a qualifying amniocentesis. The rationale for this requirement was to eliminate subjects who were more likely to respond to amnioreduction, the so-called “single amnio paradox.” Second, patients were only candidates if the TTTS presented earlier than 22 weeks’ gestation and no stage I patients were candidates for the trial. These two requirements were quite different from the Eurofetus trial in which subjects were randomized up to 26 weeks’ gestation and 52% of those entered were stage I.[188]

The study was stopped early, after 42 subjects were randomized, when the Trial Oversight Committee detected a trend in adverse outcome affecting the recipient twin in one treatment arm and recommended to the Data Safety Monitoring Board that the trial be stopped to allow biostatistical analysis of this adverse trend.

The results of the NIH TTTS trial showed no statistically significant difference in overall neonatal survival to 30 days of life (60% versus 43%, P = not significant) or neonatal survival of one or both twins in the same pregnancy (75% versus 65%, P = not significant) in cases of severe TTTS treated by either amnioreduction or selective fetoscopic laser photocoagulation. Despite these overall results, there is a statistically significantly worse fetal survival observed among recipient twins in pregnancies treated by selective fetoscopic laser photocoagulation compared with those treated by amnioreduction. This apparent conundrum can be accounted for by recipient fetal losses in the selective fetoscopic laser photocoagulation arm being balanced by increased treatment failures among recipient subjects in the amnioreduction arm. These results suggest that, in these highly selected cases of severe TTTS, neither treatment is superior to the other. Once TTTS reaches this severity, the mortality among recipients will be considerable, but the losses may occur at different times depending on treatment. The impact of TTTS severity on fetal survival is further supported by the significantly worse fetal survival among recipient twins in stages III and IV compared with stage II. One of the strongest predictors of recipient demise is echocardiographic evidence of TTTS cardiomyopathy. The losses of fetal recipients treated by selective fetoscopic laser photocoagulation usually occur within 24 hours of the procedure. In contrast, the recipients treated by amnioreduction are not lost following the procedure, but there is progressive TTTS cardiomyopathy as reflected by more recipients in the amnioreduction arm meeting criteria to be declared treatment failures. In every case, it was due to findings in the recipient twin, which met criteria for treatment failure. Taken together, these data suggest a disproportionate impact of TTTS cardiomyopathy on recipient survival in advanced stages of TTTS, no matter what treatment they receive.

Recently, Rossi and colleagues reported a Cochrane review of TTTS with a meta-analysis including data from both the Eurofetus and NIH trials. The conclusion drawn from this analysis was that selective fetoscopic laser treatment of TTTS is preferred over amnioreduction when it is available and amnioreduction when it is not.[179] The result of this analysis is likely to be skewed toward fetoscopic laser based on the small numbers of subjects included from the NIH trial (n = 40) compared to the number included from the Eurofetus trial (n = 142).

Amnioreduction is readily available, less costly and less invasive; laser therapy is only available at select institutions and requires specialized training. While it makes sense to use the former where treatment options give similar results, it would be prudent to move promptly to laser therapy if rigorous studies can prove laser has better short-term and long-term outcomes in the setting of advanced disease.

One potential limitation to the success of laser treatment is the presence of deep vascular AV anastomoses that cannot be identified endoscopically. In one study, vascular casts of 8 of 15 placentae (53%) demonstrated potentially significant atypical arteriovenous (AV) anastomoses such that two apparently normal cotyledons were actually communicating below the chorionic surface.[200] A second type of atypical AV anastomoses was noted in 11 of the 15 placentae (73%) in which shared cotyledons arise within larger apparently normal cotyledons. One would be able to see these anastomoses as shared cotyledons on endoscopy; ablating these has the potential to destroy some surrounding normal cotyledon which, in the donor's territory, could contribute to placental insuffciency.[200] It has also been recognized that in up to 20% of cases, communicating vessels on the chorionic plate are missed at the time of fetoscopic laser treatment.[136] However, only 5% of these cases were associated with persistence of TTTS. These observations point to the necessity of a careful fetoscopic inspection of the chorionic plate to be certain that no vessel has been missed.

OPEN FETAL SURGERY

The technical aspects of open fetal surgery were developed by Harrison and colleagues in extensive animal experiments using fetal sheep and rhesus monkeys.[99] Using these experimental animal models, anesthetic, tocolytic, and surgical techniques were developed and applied clinically. Innovative techniques for opening and closing the gravid uterus were developed that minimize the risks to the mother's health and future reproductive potential.[86] This included the development of a uterine stapling device to minimize myometrial bleeding.[3,15] The approach to entering the gravid uterus, fetal exposure, fetal and maternal monitoring, and anesthetic and tocolytic management are largely the same.

The indications for open fetal surgery remain relatively few and rarely do these conditions require this form of fetal intervention. As mentioned, steroids have been reported to be effective in reversing nonimmune hydrops in congenital pulmonary airway malformation (CPAM). Steroid refractory CPAM with progression of hydrops, however, remains an indication for open fetal surgery (Fig. 11-6).[37,162,192] The maternal risks with open fetal surgery are higher than with fetoscopic intervention because a large laparotomy incision is required, and because a large hysterotomy and an aggressive tocolytic regimen are required for management. Except in cases of myelomeningocele (see later), open fetal surgery is required for cases in which the life of the fetus is jeopardized. In open fetal surgery for CPAM, a thoracoabdominal incision is used for exposure and care is taken to preserve even the tiniest of compressed remaining hypoplastic lobe because CPAM is usually lobar (Fig. 11-7). Fetal survival following an open fetal surgery for hydropic CPAM is 60%. However, many losses occur when patients are referred late in the course of the disease with end-stage nonimmune hydrops. Those fetuses that are followed closely and show progression to hydrops despite steroid administration are better risk candidates if the surgery is performed earlier in the course of the disease.

Sacrococcygeal teratoma is a rare condition that occurs in only 1:25,000 live births. It can grow rapidly, precipitating high-output cardiac failure, polyhydramnios, preterm labor and/or delivery, or death in utero from nonimmune hydrops. Sacrococcygeal teratoma is almost uniformly fatal in the setting of hydrops, but successful resections in utero have been reported (Fig. 11-8).[82,108,110] The key to those successful cases has been intervention early in the development of hydrops. The goal of fetal surgery in sacrococcygeal teratoma is merely to interrupt the large vascular connections responsible for nonimmune hydrops. Care is taken to preserve the anorectal sphincter complex, and a complete section of the sacrococcygeal teratoma is not attempted. Completion of the resection of the pelvic component of the fetal sacrococcygeal teratoma must be performed postnatally. Only seven such cases have been attempted with five of seven patients surviving to delivery. These infants must be followed for at least 3 years with serial α-fetoprotein levels, serial MRIs, and physical examinations in surveillance for recurrent sacrococcygeal teratoma or malignant transformation into endodermal sinus tumor.[54,185]

Open fetal surgery has also been employed to treat other life-threatening conditions for which no other therapy exists or conventional approaches have failed, as in resection of pericardial teratoma and fetal pacemaker placement for the fetus with complete heart block that develops hydrops despite steroid and β-mimetic therapy. Perhaps the most significant change in the field of fetal surgery has been the application of this technique in non–life-threatening conditions such as myelomeningocele.[48] Although folic acid supplementation has reduced the incidence of myelomeningocele, it still occurs in up to 1 in 2000 births. Even though myelomeningocele is a serious anomaly, it is not usually fatal in utero. Early reports suggest that fetal surgery to repair myelomeningocele can

reverse the hindbrain herniation of the associated Chiari II malformation, slow the rate of enlargement of the ventriculomegaly, and perhaps decrease the need for postnatal ventriculoperitoneal shunting. The Management of Myelomeningocele Study (MOMS Trial) is an NIH-sponsored prospective, randomized clinical trial comparing open fetal treatment with conventional postnatal treatment to answer the question of whether fetal myelomeningocele repair reduces the need for postnatal shunting and improves neurodevelopmental outcome.[190] Currently, the MOMS Trial is recruiting patients with a commitment to enroll 200 infants.

Bladder outlet obstruction due to posterior urethral valves was the first structural anomaly treated by open fetal surgery. It was quickly supplanted by vesicoamniotic shunting due to the markedly less invasive nature of these shunts. While vesicoamniotic shunts can restore amniotic fluid and allow lung growth, they do not protect the kidney or the bladder from progressive injury. More than 50% of successfully treated cases go on to renal failure requiring dialysis and/or renal transplantation. Often these children are poor transplant candidates because of the fibrotic, hypertrophied, poorly compliant bladder.[13,113,205] Recently, open fetal surgery for vesicostomy creation in bladder outlet obstruction has again been employed as the most definitive means of decompressing the genitourinary tract and protecting both the bladder and the kidney.

The maternal abdomen is exposed through a low transverse abdominal incision. The fascial incision is determined by the position of the placenta. When the placenta is placed posteriorly, a midline fascial incision can be used, because the uterus does not need to be lifted out of the abdomen. In contrast, in an anteriorly placed placenta, the rectus muscles need to be divided to allow room to tilt the uterus out of the abdomen, facilitating a fundal or posterior hysterotomy. A large abdominal ring retractor (Turner-Warwick, V. Mueller, Berlin, Germany) is used to maintain exposure. Sterile intraoperative ultrasound examination is then used to map the fetal position and the placental location. The edge of the placenta is marked under ultrasound guidance using electrocautery. The position and the orientation of the hysterotomy is planned in order to stay parallel to the closest edge of the placenta and 4 to 5 cm from it.

Two different techniques have been used for performing the hysterotomy. A 2-cm incision is made through the myometrium

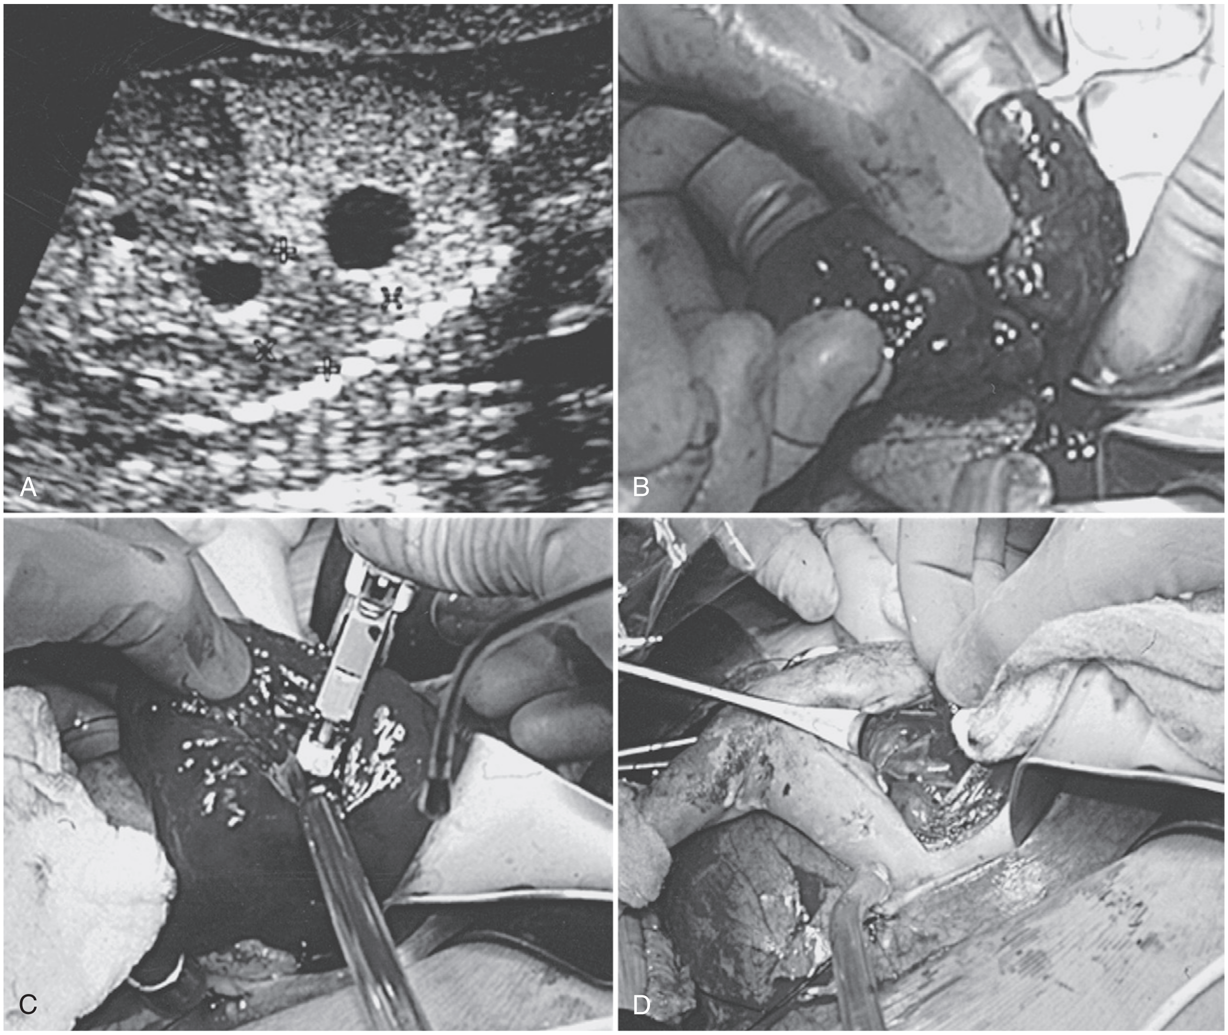

Figure 11–7. **A**, Fetal sonogram demonstrating an echogenic congenital cystic adenomatoid malformation of the lung (CCAM), with a single large cyst and compressed normal lung outlined by cursors posteriorly. **B**, Exposure of CCAM through fetal thoracotomy. **C**, Resection of CCAM from adjacent normal lung and hilum using surgical stapler. **D**, Fetal pleural cavity after resection of the CCAM. *(From Shaaban AF et al: The role of ultrasonography in fetal surgery and invasive fetal procedures,* Semin Roentgenol *34:62, 1999.)*

and amnion using electrocautery. This hysterotomy incision is then extended using a specially developed absorbable Lactimer stapler (U.S. Surgical Corporation, Norwalk, Connecticut) that is fast, hemostatic, and seals the membranes to the myometrium.[3,15] The second technique for performing a hysterotomy uses a trocar attached directly to the uterine stapling device. Two traction sutures are placed to elevate the membrane and myometrial wall from the fetus, and a specially designed trocar attachment that fits on the anvil of the uterine stapling device is inserted directly into the amniotic cavity under ultrasound guidance.

Once the hysterotomy is performed, saline is infused to avoid cord compression. A red rubber catheter attached to a level I rapid volume infusion device is inserted into the amniotic cavity, which delivers a continuous stream of normal saline warmed to 37°C. The appropriate fetal part is then exposed, leaving the rest of the fetus entirely within the womb. A miniaturized pulse oximeter is wrapped around the fetal palm and protected with a clear plastic adhesive, then shielded from extraneous light with sterile foil wrapping or Coban.

Once the specific defect has been repaired, the fetal part is then returned to the uterus. Full-thickness number 1 PDS stay sutures are then placed along the length of the hysterotomy. As the staples are made of polyglycolic acid and are absorbable, they are left in place to avoid bleeding from the hysterotomy edges. A watertight three-layer uterine closure is then performed, using a running 0 PDS. Just before completing the first layer, 400 to 500 mL of warm normal saline containing 500 mg of oxacillin is instilled into the amniotic cavity to restore the amniotic fluid volume to a deepest vertical pocket of 3 to 5 cm. The stay sutures are then tied and the maternal laparotomy incision is closed in layers. A subcuticular maternal skin closure is used with a transparent adhesive dressing to facilitate postoperative monitoring by a tocodynamometer and ultrasound examination. The hysterotomy used

for open fetal surgery remains a weakened area in the myometrium, which is at risk for rupture during active labor with subsequent pregnancies. The nature of the hysterotomy used in all open fetal surgeries mandates that all future deliveries be by cesarean section before onset of labor.

Tocolysis begins as soon as the uterus is closed with a 6-g load of magnesium sulfate over 1 hour, which then continues at 2 g per hour, or at a higher dose, as clinically indicated by uterine irritability. As the mother emerges from deep anesthesia with isoflurane, there is a tendency for uterine tone to return and for uterine contractions to be observed. To supplement the magnesium sulfate, rectal indomethacin on a schedule of 25 to 50 mg every 4 to 6 hours is also used for the first 48 hours. The use of indomethacin requires close fetal monitoring by daily fetal echocardiography for ductal constriction. Patient-controlled analgesia is also an essential part of the tocolytic management. Maternal pain is reflected in increased uterine irritability. A continuous fentanyl infusion may be supplemented by bupivacaine for postoperative pain control may be delivered through an epidural catheter, with patient-controlled rescue doses. The systemic levels of fentanyl achieved with the use of this epidural technique are sufficient to cross the placenta and provide fetal analgesia as well.

Far and away the most difficult problem in the management of the maternal-fetal patient following fetal surgery is the control of preterm labor. The large hysterotomy necessary for these procedures uniformly results in preterm labor. This has led to the development of an aggressive tocolytic regimen that often includes combinations of indomethacin, isoflurane anesthesia, magnesium sulfate, terbutaline, calcium-channel blockers, and most recently intravenous nitroglycerin as a nitric oxide donor.[98] Despite aggressive tocolytic therapy, the median interval from fetal surgery to delivery is only 8 weeks, with a range of 1 to 15 weeks.[89]

Unlike any other procedure, with the possible exception of organ transplantation from a living, related donor, fetal surgery exposes two patients, the mother as well as the fetus, to the risks of anesthesia, surgery, hysterotomy, and postoperative tocolysis. The most important factor in fetal surgery is the assurance of the mother's safety. Toward this end, extensive maternal monitoring of arterial blood pressure and pulse oximetry is necessary. In addition, appropriate fetal monitoring includes telemetric fetal heart monitoring, serial sonography, and surveillance of preterm labor by external tocodynamometer. Optimal monitoring of both patients can best be managed in a setting that combines the capabilities and expertise of both an intensive care unit and a labor floor, in a fetal-maternal intensive care unit.[116]

Although the benefits to the fetus with an otherwise lethal congenital malformation are obvious, there are no direct benefits to the mother, who must assume the risks of fetal surgery and obligatory delivery by cesarean section. There have been no reports of maternal deaths related to open fetal surgery, but the potential for maternal morbidity is formidable. Among the 42 cases reported by Harrison and associates, five patients have required perioperative blood transfusions. Amniotic fluid leaks were observed in five cases, two via the hysterotomy site and requiring reoperation, and three via the vagina. Preterm labor was uniformly observed, and the majority of the morbidity occurred as a result of aggressive treatment of preterm labor, including pulmonary edema induced by tocolytic agents.[89] In addition, long-term complications in mothers who undergo fetal surgery include uterine rupture with labor during subsequent pregnancies, as has been seen in two patients. Because the incision used in fetal surgery is not in the lower uterine segment, there is the potential for uterine rupture with labor, so all future deliveries should be by cesarean section. The specific anatomic malformations in which open fetal surgery has already been used are listed in Table 11-3.

EXIT PROCEDURE

The central principle of the ex utero intrapartum treatment (EXIT) procedure is controlled uterine hypotonia to preserve the uteroplacental circulation. The EXIT procedure was described for reversal of tracheal occlusion in fetuses with severe congenital diaphragmatic hernia (CDH).[156] These cases required neck exploration for the removal of the tracheal clips, with maintenance of uteroplacental blood flow until the fetal airway was secured by endotracheal intubation. Experience with the EXIT technique demonstrated fetal and maternal hemodynamic stability and soon led to expanded indications for its use. The indications have broadened to include giant fetal neck masses, fetal mediastinal or lung masses, such as congenital cystic adenomatoid malformation (CCAM), and congenital high airway obstruction syndrome (CHAOS), among others (Box 11-1). A common misconception is that an EXIT procedure is merely a cesarean section. The goals during the latter procedure are to (1) maximize the uterine tone to prevent postpartum hemorrhage and (2) minimize the transplacental diffusion of inhalational anesthetic agents to avoid neonatal depression (if performed under general anesthesia). In contrast, the goals during the EXIT procedure are to (1) achieve a state of uterine hypotonia so to maintain the uteroplacental circulation using deep general anesthesia, (2) preserve uterine volume so to prevent placental abruption, (3) reach a deep plane of maternal anesthesia but maintain normal maternal blood pressure, and (4) achieve a surgical level of fetal anesthesia without cardiac depression. In addition, the EXIT procedure requires synchronized team work involving multiple disciplines, including at least one or two pediatric surgeons or a pediatric otolaryngologist, a maternal-fetal medicine specialist or obstetrician, an echocardiographer, a neonatologist, two anesthesiologists, two circulating nurses, and two scrub nurses. Unlike standard obstetric anesthetic practice in which regional anesthesia is the rule, general anesthesia

is the technique of choice for patients undergoing the EXIT procedure. As with any fetal surgical procedure, the EXIT procedure involves the treatment of two patients: the mother and her baby. For this reason, we usually have one anesthesiologist for the mother and another for the baby. There are a number of maternal and fetal anesthesia considerations that must be managed. The physiology of pregnancy contributes to a number of maternal and fetal anesthetic risks. The mother is at increased risk for aspiration pneumonitis due to pregnancy-related reduction of lower esophageal sphincter pressure, the increased pressure of the gravid uterus on the stomach, and increased gastric acid production. The cardiovascular system is also affected during pregnancy. A decrease in the preload during supine positioning can cause maternal hypotension, decreased uterine artery perfusion, and thus fetal hypoxia. It is therefore important to position the mother with a left uterine displacement to maximize venous return to the heart and preserve an adequate maternal cardiac output. In pregnancy there is an expanded blood volume, but a lower hematocrit and an increase in peripheral venous capacity. Pregnancy also affects pulmonary function, with a decrease in functional residual capacity that puts the mother at an increased risk for hypoxia. For these reasons, maternal anesthesia is induced through a rapid-sequence technique using a combination of thiopental (5 mg/kg), succinylcholine (2 mg/kg), and fentanyl (1 to 2 μg/kg) administered intravenously. This is followed by immediate endotracheal intubation. Paralysis is maintained using intravenous vecuronium titrated by peripheral nerve stimulation.

FETAL ANESTHESIA CONSIDERATIONS

Support of the fetus during the EXIT procedure depends entirely on the preservation of uteroplacental gas exchange. Both uterine and umbilical artery blood flow influence fetal oxygenation. Uterine artery blood flow is affected by maternal systemic blood pressure and myometrial tone. Volatile anesthetics used during the EXIT procedure not only decrease myometrial tone but also tend to decrease both maternal blood pressure and placental blood flow. This can result in a decrease in fetal oxygenation.[138] Maintenance of maternal blood pressure within 10% of baseline is therefore critical for adequate fetal oxygenation during the EXIT procedure. Maintenance of maternal blood pressure is achieved using ephedrine to counterbalance the hypotensive effects of the high concentrations of inhalational agents used in EXIT procedures. Ephedrine acts selectively on peripheral vascular resistance and spares the placental circu1ation.[67] Uteroplacental gas exchange is also dependent on umbilical artery blood flow, which is influenced by fetal cardiac output and placental vascular resistance. Preservation of fetal cardiac output is thus important in maintaining fetal oxygenation.

The cardiovascular physiology of the fetus is different from that of full-term neonates in that the cardiac output is more dependent on heart rate rather than on stroke volume. In addition, high vagal tone and low baroreceptor sensitivity cause the fetus to respond to stress with a decrease in heart rate. The fetus primarily relies on increased heart rate to increase cardiac output and blood flow redistribution in response to stress. This preserves oxygenation for the brain at the expense of the rest of the body. In addition to the peculiar characteristics of fetal physiology, inhalational anesthetics also cause a direct fetal myocardial depression, vasodilatation, and changes in arteriovenous shunting, all of which can lead to fetal hemodynamic instability.[14] These physiologic differences and responses to anesthetic agents require continuous fetal monitoring to ensure uncompromised uteroplacental gas exchange and fetal well-being.

The inhalational anesthetic regimen used during the EXIT procedure passes through two different stages. Anesthesia is at first maintained with 0.5 MAC (minimal alveolar concentration) of desflurane, isoflurane, or sevoflurane in oxygen, and is then increased to 2 MAC before maternal incision. Recently, total intravenous anesthesia has been used to prevent transplacental passage of inhalational agent, which may act as a fetal myocardial depressant. An inhalational agent is used only at time of hysterotomy to achieve the desired relaxation of uterine tone. Occasionally, a tocolytic is given to augment the uterine relaxation. A number of tocolytic agents can be used as an adjunct to inhalational agents, including indomethacin, terbutaline, or nitroglycerine. Indomethacin may also prevent prostaglandin-mediated increases in placental resistance independent of its effects on uterine tone.[112] Maintenance of uterine volume is also important to prevent uterine contraction. This is accomplished by preventing the fetus from completely delivering and by the use of amnioinfusion with warm Ringer's lactate solution administered via a rapid infuser to prevent cord compression.

The second critical stage of the anesthetic technique comes just before clamping of the cord and ending the EXIT procedure. During this stage, coordination between the surgical and anesthesia teams is crucial to prevent uterine atony and excessive maternal bleeding. The volatile anesthetic is decreased to 0.5 MAC or turned off entirely to allow uterine tone to return to normal. This is followed by administration of oxytocin 20 units in 500 mL of normal saline intravenously as a bolus followed by 10 units in a 1000-mL drip titrated to enhance uterine contraction. If required, further measures are taken to decrease the risk of uterine atony. These measures include uterine massage and administration of 0.25 mg methergine and 250 μg carboprost ($F_{2\alpha}$ prostaglandin) via intramuscular or intravenous injection. After skin closure, the inhalational anesthetic is discontinued and 100% oxygen is administered. Maternal paralysis is reversed by the use of glycopyrrolate (10 μg/kg) and neostigmine (0.7 mg/kg), and the patient is extubated after spontaneous breathing is observed.[16]

Fetal anesthesia is provided primarily through the transplacental passage of the volatile anesthetics. However, this takes about an hour to reach 70% of the maternal levels. As such, before fetal incision, a cocktail comprising 10 to 20 μg/kg fentanyl, 20 μg/kg atropine, and 0.2 mg/kg vecuronium is administered intramuscularly to supplement anesthesia and provide for postoperative analgesia.

Close maternal and fetal monitoring during the EXIT procedure aim at the early recognition and management of problems as they arise. Maternal monitoring includes invasive arterial blood pressure monitoring (arterial line) to recognize possible maternal hypotension that will jeopardize fetal oxygen transport, continuous electrocardiography, pulse oximetry, and end-tidal CO_2 monitoring.

Continuous fetal monitoring is of paramount importance during the EXIT procedure. Fetal arterial saturation is monitored by a reflectance pulse oximeter placed on the fetal hand and wrapped with foil to decrease ambient light exposure.[49] Normal fetal arterial saturation is 60% to 70%, although values greater than 40% represent adequate fetal oxygenation. Continuous intraoperative fetal echocardiography is also used to monitor fetal cardiovascular function.[181] The use of fetal echocardiography helps identify early problems such as decreased filling, fetal bradycardia, decreased myocardial contractility, ductal constriction, and atrioventricular valve incompetence (Fig. 11-9). These are all signs of fetal distress that require prompt treatment. Fetal arterial or venous blood gases may be obtained through umbilical vessel puncture during periods of fetal distress to guide in therapy. Intravenous access is essential to allow administration of fluids, blood, or medications for inotropic support when needed.

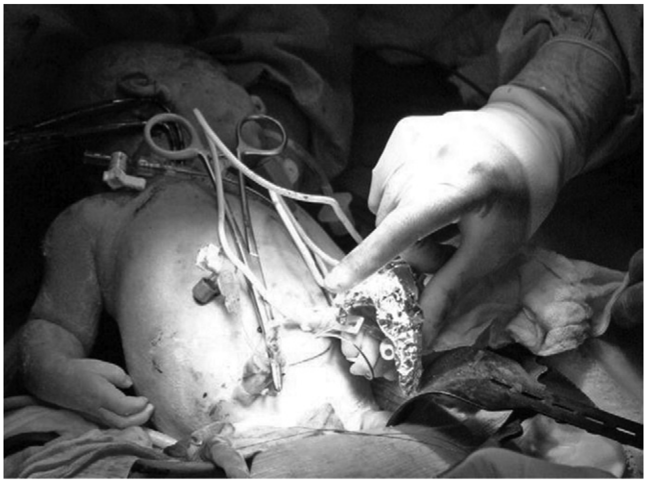

Figure 11–9. An intraoperative view during an ex utero intrapartum treatment procedure demonstrating continuous fetal monitoring using a sterile echocardiography, reflectance pulse oximetry, and intravenous access lines. See color insert.

The decision to enter the abdomen through a low transverse skin incision or through a midline fascial incision is based on the placental location, predicted site of hysterotomy, and the indication for performing the EXIT procedure. The incision of choice is usually a low transverse abdominal incision unless anterior position of the placenta necessitates a posterior hysterotomy. In the latter case, a midline laparotomy is required. After laparotomy, the uterus is examined for adequacy of myometrial relaxation, and concentration of inhalational agents is adjusted as necessary. Before fashioning the hysterotomy, precise sonographic mapping of the placental edge is crucial to avoid placental injury and hemorrhage. A sterile intraoperative ultrasound is used to map the placental borders. This is performed while considering the position of the fetal head and neck to avoid excessive fetal manipulation after hysterotomy. The position of the hysterotomy is dictated by the placental location. A low anterior placental site precludes a low transverse hysterotomy and may necessitate a posterior approach for the hysterotomy. Special considerations are important in cases of severe polyhydramnios. Amnioreduction in these cases is necessary to avoid underestimation of the proximity of the placental edge to the hysterotomy. To adequately manipulate the fetus, it is sometimes necessary to decompress any accompanying fetal ascites or cystic mass. This can be achieved by using a 20- or 22-gauge spinal needle under ultrasound guidance. In some instances, the use of amnioinfusion and fetal version before hysterotomy facilitate the exposure.[106] During EXIT procedures, hysterotomy is performed using a specially designed uterine stapler (U.S. Surgical Corporation, Norwalk, Conn) to decrease the incidence of bleeding.[15] Following hysterotomy, maintenance of uterine volume is one of the most important steps in an EXIT procedure. This is done to decrease the likelihood of uterine contraction and placental abruption, thus maintaining continuous maternal-fetal oxygen transfer. Warm Ringer's lactate solution is infused after the hysterotomy to maintain the uterine volume and prevent cord compression. Limited exposure of the fetus during the EXIT procedure also helps maintain the uterine volume and fetal temperature. Only the head, neck, and shoulders are exposed while keeping the remainder of the fetus and the cord intrauterine.

The most important aspect of fetal airway management during an EXIT procedure is preparedness for every contingency. In that one can never assume that the fetus will only require direct laryngoscopy and intubation, we have developed an airway algorithm.

In addition to the basic instruments and setup, the following items should be available on a separate airway table managed by a second scrub nurse: direct laryngoscopy supplies with Miller 0 and 00 blades, armored endotracheal tubes (ETT) appropriate for the size of the fetus, endotracheal tube exchangers, 2.5- and 3-French feeding tubes for surfactant administration, 2.5 or 3 rigid bronchoscope, a flexible bronchoscope, and a major neck tray for formal tracheostomy or mass resection.

Direct laryngoscopy and endotracheal intubation should be the first option for securing a fetal airway during EXIT procedures (Fig. 11-10). In cases in which there is distortion of the normal anatomy, flexible and/or rigid bronchoscopy may be necessary to visualize and diagnose abnormal airway anatomy. The glottis is sometimes displaced cephalad above the level of the soft palate; in such cases, flexible bronchoscopy via the nares may be helpful. In other cases, mass effect may shift the glottis severely from its normal midline position. An armored endotracheal tube can be placed over the flexible bronchoscope or rigid lens and can be used to place the ETT beyond the level of obstruction. If this fails to secure an airway, then retrograde intubation becomes the next option in which a tracheotomy is performed through limited neck dissection. Using a Seldinger technique, an ETT exchanger is passed retrograde until seen in the oropharynx. The ETT is passed antegrade over the ETT exchanger and the tracheotomy repaired. In the case of large neck masses, traction by an assistant may lift the mass off the airway. This permits an armored ETT to be passed beyond the level of obstruction. If there is severe compression, release of the strap muscles may be required to permit passage of an armored ETT beyond the area of airway obstruction. Airway control is sometimes impossible even after all these techniques have been attempted. In these cases, reflection of the mass off the airway or resection of the mass to facilitate formal surgical tracheostomy may be necessary. Proper positioning of the tracheostomy is extremely important, especially in cases of giant neck masses in which the trachea is pulled out of the chest by neck hyperextension. It is not uncommon to find the carina at the level of the thoracic inlet due to the opisthotonic position of the head caused by a neck mass. Care should be taken to place the tracheostomy tube no lower than the second to third tracheal rings.

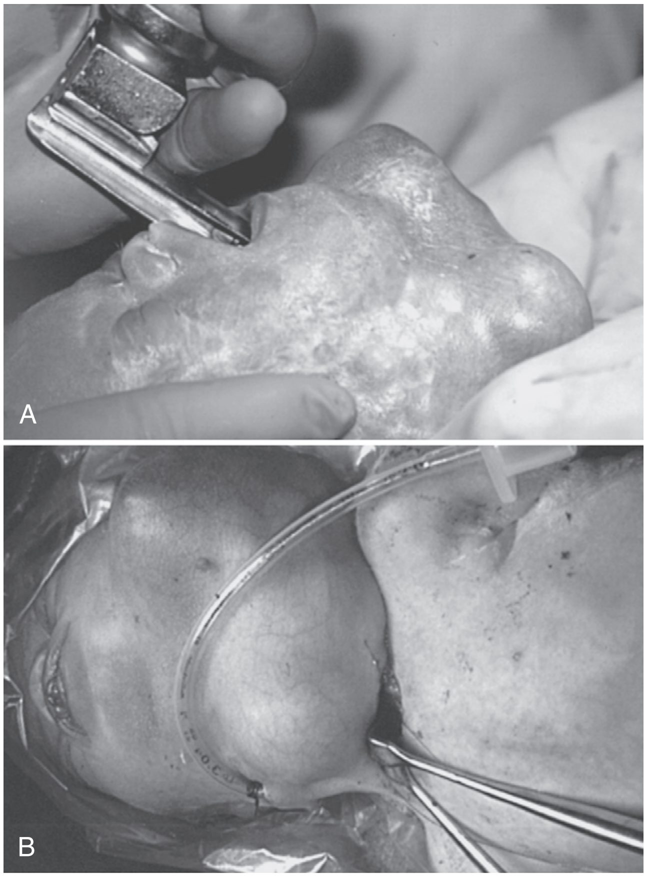

Figure 11–10. A, Direct laryngoscopy performed during ex utero intrapartum treatment (EXIT) procedure on a fetus with airway compromise caused by a giant cervical teratoma. B, Tracheostomy performed during the EXIT procedure, requiring tunneling of an endotracheal tube through the soft tissues of the neck because of the severe distortion of the fetal airway. (*From Shaaban AF et al: The role of ultrasonography in fetal surgery and invasive fetal procedures,* Semin Roentgenol *34:62, 1999.)*

After securing the airway, it is prudent to confirm the position of the ETT or tracheostomy tube relative to the carina using flexible bronchoscopy. This is particularly important in patients with cervical or mediastinal masses. If required, surfactant can then be administered by a feeding tube passed through the ETT. The fetus is then ventilated by hand. Finally, umbilical arterial and venous access catheters can be placed and the cord clamped. Coordination between the surgical team and the anesthesiologists is of paramount importance at this moment to ensure adequate return of the uterine tone and proper hemostasis. The newborn is either taken to an adjoining operating room for further resuscitation and completion of the neck mass resection or to the neonatal intensive care unit for further resuscitation and stabilization.

The EXIT procedure is associated with an increased potential risk of maternal bleeding due to uterine hypotonia induced by high concentrations of inhalational agents. These high levels may also induce maternal hypotension. It is important to ensure the prompt return of uterine tone at the conclusion of the EXIT procedure to minimize maternal hemorrhage. Although uterine atony remains a significant risk and there is the potential need for hysterectomy, in our experience, the mean blood loss with EXIT procedures has been equivalent to that observed in cesarean sections. Early in our experience, we had to transfuse a patient in whom polyhydramnios caused us to underestimate the proximity of the placenta to the hysterotomy. In a review of the experience of clinicians at the UCSF, a slightly higher incidence of wound infection was reported with EXIT procedures than with cesarean sections. Although the EXIT procedure is specifically designed to optimize outcomes for the fetus, if it is not performed appropriately, there is also the potential for fetal complications. These are primarily related to failure to

TABLE 11–4 Pitfalls of the EXIT procedure

Failure to achieve adequate uterine relaxation	Compromise uteroplacental gas exchange
Failure to treat polyhydramnios	Inaccurate mapping of placental edge—hemorrhage
Failure to plan for fetal position relative to hysterotomy	Difficult exposure for delivery of head
Failure to use uterine staples	Maternal hemorrhage
Failure to use deep inhalation anesthesia	Inadequate uterine relaxation—poor uteroplacental gas exchange
Failure to maintain adequate maternal blood pressure	Poor uterine artery perfusion or compromised uteroplacental gas exchange
Failure to recognize cord compression	Fetal bradycardia
Failure to recognize placental abruption	Fetal hemorrhage
Failure to make airway first fetal priority	May have to end EXIT acutely due to abruption, or persistent fetal bradycardia
Failure to be prepared for every airway challenge	Fetal death. Must not assume that laryngoscopy will be successful. Must be prepared for bronchoscopy, tracheostomy, and/or mass resection
Failure to allow sufficient time for return of uterine tone	Uterine atony and maternal hemorrhage
Failure to use armored endotracheal tube (ETT)	Collapse of fetal endotracheal tube by tumor compression
Failure to confirm ETT tip position bronchoscopically	Malpositioned ETT. This is especially important with cervical or mediastinal tumors
Failure to maintain uterine volume	Acute loss of uterine volume may predispose to placental abruption.
Failure to perform adequate intrapartum fetal monitoring	Unrecognized fetal distress or bradycardia
Failure to recognize maternal indications for terminating EXIT	Maternal hemorrhage
Failure to recognize fetal indications for terminating EXIT	Fetal bradycardia or arrest, fetal hemorrhage, or hypoxic brain injury

preserve uteroplacental gas exchange due to cord compression, placental abruption, or loss of myometrial relaxation (Table 11-4).

SUMMARY

The evolution of fetal therapy holds tremendous promise to change the prenatal natural history and improve not only perinatal survival but also potential long-term outcomes. However, these efforts in developing innovative fetal treatment should not be mistaken for establishing fetal therapy as the standard treatment for any condition. Critical appraisal of the potential maternal and fetal risks of fetal intervention must be carefully weighed by all parents and caregivers considering these options. Nevertheless, collateral advances in multiple disciplines have occurred as a result of fetal interventions. Furthermore, the contribution of fetal surgery to advances in prenatal care and perinatal management have implications far beyond the narrow sphere of fetal therapy. With improved knowledge of perinatal disorders and extensive investigation in diminishing the potential risks of fetal intervention, the field of fetal therapy will continue to expand and provide new and exciting therapeutic options for the unborn patient.

CHAPTER 12

Occupational and Environmental Risks to the Fetus

Cynthia F. Bearer

Occupational and environmental risks to the fetus are increasing in importance. In 2008, women constituted 46.5 percent of the total workforce (approximately 68 million female workers).[98] Of working women, 57 percent are of reproductive age (16-45 years).[99] Two thirds of women worked during their pregnancy with their first child between 2001 and 2003.[101] The actual number of working women who give birth each year is unknown because no U.S. Department of Labor or Bureau of Labor Statistics figures exist to quantify the percentage of working women who give birth. The number of births in 2008 was 4.25 million. Assuming that multiple births are negligible, approximately 2.8 million infants were born to mothers employed outside the home.

Environmental exposures are increasing as population and economic needs continue to expand. In 1900, there were 1.25 billion people on Earth. This number doubled by 1950, then it doubled again to 5 billion by 1987. There are 6.8 billion (2008) people on Earth, and this number will increase to more than 9 billion by 2050.[97] The pressures of population growth on the environment are reflected in increasing need for land, water, food, and fuels.

With more people and increasing economic expansion come the problems of emissions and pollution from daily living, industry, commerce, and agriculture.[104] Land is overused; water, air, food, and soil are contaminated. Every human on this planet is exposed to chemicals and other agents. The U.S. Centers for Disease Control and Prevention (CDC) is monitoring 212 environmental pollutants in human blood and urine (Fourth National Report on Human Exposure to Environmental Chemicals: 2009, www.cdc.gov/exposurereport/, date accessed 2/10/2010). This chapter describes the various types of exposures (nonconcurrent and concurrent with pregnancy), the unique pharmacokinetics of the fetus, and the spectrum of adverse outcomes known to be associated with occupational and environmental exposures (Fig. 12-1).

EXPOSURES NOT CONCURRENT WITH PREGNANCY

Environmental exposures that affect newborns may occur before conception and possibly before conception of the parents. The main effect of these exposures may be on the ovum or sperm, which leads to the development of an abnormal fetus. A woman's exposure may result in an exposure to the developing fetus by the ongoing elimination of the chemical from the mother's body. Because the initial exposure is experienced by the mother or father or prior generation before conception, these exposures are not concurrent with the pregnancy. For some chemicals, such as organohalogens, the fetus can be affected by nonconcurrent and concurrent maternal exposures.

Preconceptional Effects

EXPOSURES AFFECTING THE EPIGENOME

The epigenome is the methylation of DNA or post-translational modifications of histones that regulate how genes are expressed.[31] The epigenome is stable and heritable, and might be a target for environmental exposures occurring in a previous generation, which are then inherited by the unexposed offspring. Vinclozolin, a commonly used fungicide, causes infertility and prostate tumors in mice exposed in utero via alteration in the epigenome. Male offspring pass these traits on to their offspring. In contrast, offspring of the prenatally exposed females are normal. The changes in the epigenome are within the male germline. The transgenerational effects have been measured in offspring of the males out to the third generation after the exposure, which is the first generation to have not been directly exposed in utero.[1]

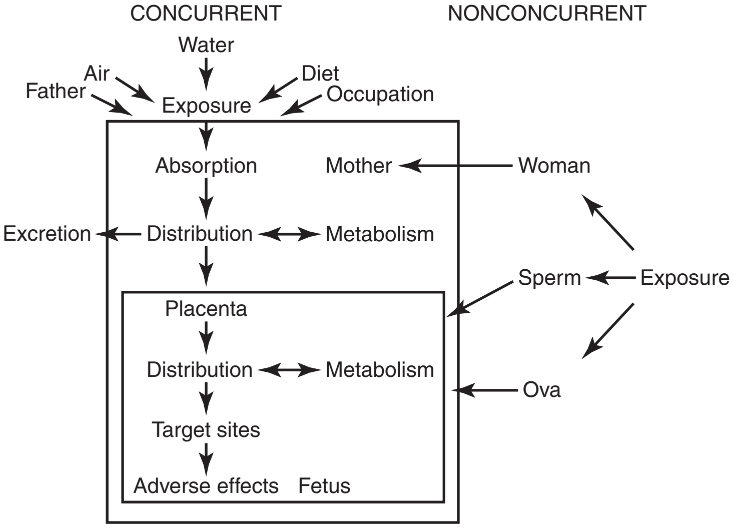

Figure 12–1. Maternal concurrent and nonconcurrent exposures and fetal exposure.

Similarly, the agouti mouse contains a coat color gene that is controlled by a promoter containing a methylation site. If the pregnant mice are fed normal rat chow, the offspring have a yellow coat and develop obesity. If the mice are fed a diet supplemented with methyl donors such as folic acid, they develop the normal brown color coat. Maternal exposure to bisphenol A, an endocrine disruptor that leaches from plastic, shifts the distribution of the offspring's coat color to yellow. This effect can be reversed by supplementing the maternal diet with choline, folate, or other methyl donors.[28] Such changes in coat color are heritable in subsequent generations, but the mechanism does not seem to be through heritable changes in DNA methylation and remains unknown.[28] Such changeable methylation patterns have yet to be discovered in humans.

EXPOSURES AFFECTING THE OVUM

Ova begin to develop in early fetal life. During female fetal development, the oogonia are formed by meiotic division. Before birth, all oogonia have developed into primary oocytes and have completed the prophase of the first meiotic division (Fig. 12-2).[58] At the end of prophase, the chromosomes are condensed, and spindle fibers connect them to the centrioles, which have reached the poles of the cell. The nuclear membrane has disappeared.[26] The oocyte remains in this state until puberty and can remain for 50 years.

The oocyte may be vulnerable to environmental exposures. This hypothesis is supported by the increasing incidence of nondisjunctional events with increasing maternal age and with prolonged environmental exposure. Environmental exposures to the oocyte have been shown in two studies.[96] Xenobiotics (chemicals foreign to the metabolic network of the body) were measured in samples of human follicular fluid collected during oocyte harvesting for in vitro fertilization. Concentrations of representative xenobiotics from one study are shown in Table 12-1. A second study showed an association between failed fertilization and the concentration of pp′DDE (a metabolite of DDT) in follicular fluid.[113]

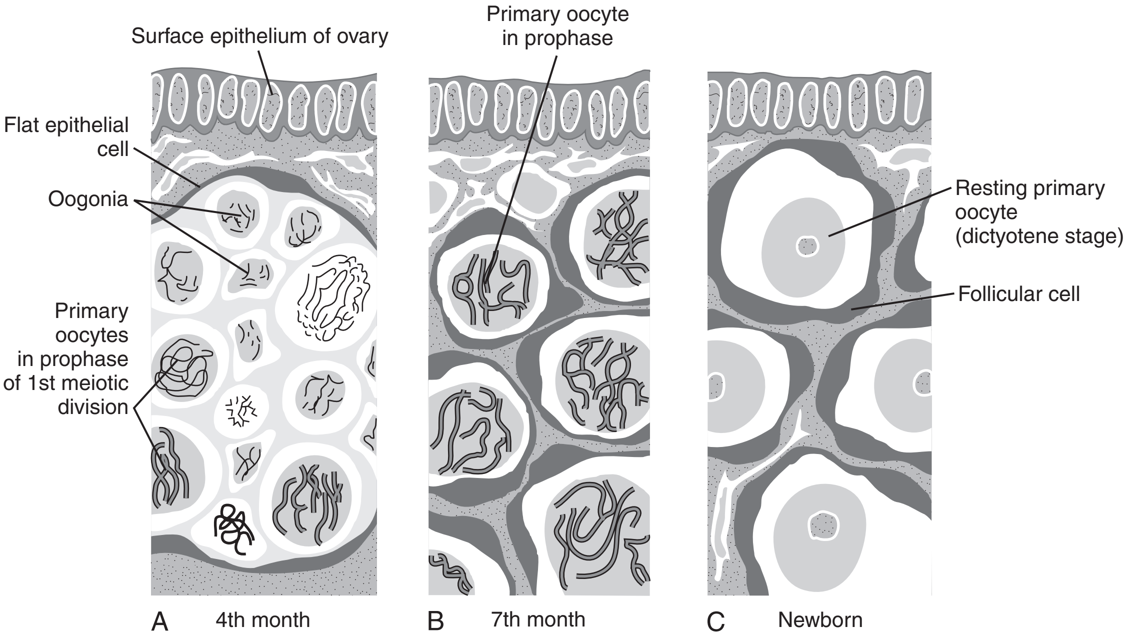
The easiest outcome to measure is loss of fertility. Loss of ova from such exposures can reduce fertility as reported in women born to mothers who smoke.[71,102] Few outcome studies on environmental exposures have been reported, however, owing to the lengthy period from exposure to outcome in such transgenerational studies. The population of women who took diethylstilbestrol (DES) during pregnancy is an exception because the exposure was well documented.[42,43] Several reports on transgenerational effects from DES exposure (effects in individuals whose grandmothers took DES during pregnancy [i.e., DES grandchildren]) have been published. These effects include increased incidence of hypospadias in grandsons (prevalence ratio of 21.3, 95% confidence interval [CI] 6.5-70.1)[52] and prematurity of DES grandsons and granddaughters.[42,52]

Paternal Effects

In contrast to effects on ova, effects on sperm can be measured easily in the next generation, so there is more evidence in the literature to suggest that paternal exposures before conception may constitute a risk to the fetus. The sperm itself represents a vulnerable stage to the effects of mutagens; in its final form, the sperm has no DNA repair mechanisms.

Cancer is not usually thought to be a result of preconceptional or prenatal exposures. New data suggest, however, that the sperm may be a vulnerable target for carcinogens. The relationship of the risk of cancer in the offspring and paternal occupation (as a proxy for exposure) has been extensively studied. One study reported increased risk of central nervous system tumors with paternal occupational exposure to pesticides (relative risk [RR] 2.36; 95% CI 1.27-4.39) and work as a painter (RR 2.18; 95% CI 1.26-3.78),[32] and increased risk of leukemia with paternal woodworking (RR 2.18, 95% CI 1.26-3.78).

In 1998, 48 published studies representing more than 1000 specific combinations of occupation and cancer were reviewed.[21] Important findings were that occupations and exposures of fathers were investigated much more frequently



Surface epithelium of ovary
Primary oocyte in prophase
Flat epithelial cell
Oogonia
Primary oocytes in prophase of 1st meiotic division
Resting primary oocyte (dictyotene stage)
Follicular cell
A 4th month
B 7th month
C Newborn

Figure 12–2. Segment of ovary at different stages of development. **A**, At 4 months' gestation, oogonia are grouped in clusters in the cortical part of the ovary. Some show mitosis, whereas others have already differentiated into primary oocytes and have entered prophase of first meiotic division. **B**, At 7 months' gestation, almost all oogonia are transformed into primary oocytes in prophase of first meiotic division. **C**, At birth, oogonia are absent. Each primary oocyte is surrounded by a single layer of follicular cells, forming primordial follicle. Oocytes have entered the dictyotene stage, in which they remain until just before ovulation, when they enter metaphase of first meiotic division. *(From Langman J:* Medical embryology, *Baltimore, 1975, Williams & Wilkins, p 11, with permission.)*

than those of mothers, and the studies have limitations related to the quality of the exposure assessment, small numbers of exposed cases, multiple comparisons, and possible bias toward the reporting of positive results. Despite these limitations, evidence was found for associations of childhood leukemia with paternal exposure to solvents and paints and with paternal employment in occupations related to motor vehicles.

The studies on the association of birth defects with paternal occupation also have been reviewed and found to have many of the same limitations as the studies of paternal occupation and cancer.[18] Birth defects were repeatedly reported to be associated, however, with men in several common occupations (janitors, painters, printers, firefighters, and workers in occupations exposed to solvents or related to agriculture).

TABLE 12–1 Xenobiotics in Human Follicular Fluid

Contaminant	MEAN CONCENTRATION (PPB)	SEM
Lindane	1.22	0.18
Total DDT	3.37	0.44
PCBs	8.03	0.88
Hexachlorobenzene	2.59	0.24
Dieldrin	0.13	0.03
Heptachlor epoxide	0.12	0.02

DDT, dichlorodiphenyltrichloroethane; PCBs, polychlorinated biphenyls; PPB, parts per billion; SEM, standard error of the mean.
From Trapp M et al: Pollutants in human follicular fluid, *Fertil Steril* 42:146, 1984.

Additional evidence that paternal exposures may result in fetal abnormalities comes from observations that certain birth defects and diseases are associated with older fathers. These abnormalities include ventricular septal defects, atrial septal defects, and situs inversus.[59] The strongest association between advanced paternal age and birth defects is with achondroplasia.[85] One study found that 2% of children born to men 50 years or older have schizophrenia.[64] The data on paternally mediated effects have been reviewed extensively.[54,62,72]

There may be several mechanisms by which paternal preconceptional exposures affect the fetus. It seems that increasing autosomal dominant mutations occur with advanced paternal age; the incidence of Apert syndrome and achondroplasia increases with paternal age. Another possible mechanism for paternally mediated effects is the impairment of a paternal gene that is necessary for the normal growth and development of the fetus. In animals and humans, the fetus requires genes derived from the father and the mother, a phenomenon called *genetic imprinting*. Replacement of the father's genetic material with a second copy of the mother's genetic material (uniparental disomy), or vice versa, results in a nonviable conceptus.[38]

One example of a defect in genetic imprinting is Prader-Willi syndrome, caused by a functional mutation in paternal 15q, resulting in inactivation of the genes in that region of the chromosome. Angelman syndrome occurs if maternal 15q is affected. Environmental factors may play a role in functional uniparental disomy and lead to paternally mediated effects on the fetus. Two studies have shown an association between paternal exposure to hydrocarbons and Prader-Willi syndrome.[16,94] In one study, approximately 50% of the fathers of patients with Prader-Willi syndrome were occupationally exposed to hydrocarbons.[16]

Another novel mechanism for preconceptional paternally mediated effects has been proposed by Yazigi and associates.[111] They found a high-affinity binding site for cocaine on sperm and postulated that sperm acted as a transporter of cocaine into the ovum.

Secondary Fetal Exposure: Maternal Body Burden

Nonconcurrent fetal exposure can result from either ongoing excretion of xenobiotics from maternal storage compartments or mobilization of contaminated compartments during pregnancy. Adipose tissue and skeletal tissue are known storage sites for chemicals.

POLYCHLORINATED BIPHENYLS

Organohalogens are extremely stable chemicals in the environment and in biologic systems. They bioaccumulate, becoming concentrated in tissues as they move up the food chain. Polychlorinated biphenyls (PCBs) are an example of this kind of chemical. PCBs are ubiquitous in the environment because of their widespread use as liquid insulators for transformers and capacitors, and because of their resistance to chemical and biologic breakdown. Their global distribution was first reported in 1966.[50] Their production peaked in 1970 and subsequently declined as many countries banned or limited their use.[47]

Two major human poisonings have occurred through rice oil that was contaminated with PCBs, one in Japan in 1968 (called *yusho disease*) and one in Taiwan in 1979 (called *yu-cheng disease*). In Taiwan, approximately 2000 adults had an illness characterized by hyperpigmentation, acne, and peripheral neuropathy. Of the first 39 hyperpigmented children born to poisoned women, 8 died.[46] In 1985, a cohort of 117 children born since the 1979 episode was found to have an excess of ectodermal defects and developmental delay.[82] Very few of these children were in utero during the actual poisoning episode. Their exposure to PCBs was from the elevated maternal body burden.

In a later report,[17] Taiwanese children born 6 years after maternal exposure were as developmentally delayed as children born within 1 year of maternal exposure (Fig. 12-3). The developmental delay persisted in these children at all times measured. These children had significant adverse effects from a maternal exposure to PCBs that occurred 6 years before their birth.

The cognitive defects seen in the children with yu-cheng disease are comparable to the cognitive defects observed in American children exposed to higher levels of background PCBs. In North Carolina, small motor deficits were observed in children up to 2 years old who had been prenatally exposed to PCBs through maternal body burden acquired from background exposure.[33] In Michigan, short-term memory deficits were measured in 4-year-old children who had elevated cord blood levels of PCBs and whose mothers had regularly consumed sport fish contaminated with PCBs.[48] Further follow-up of these children at 11 years old showed that the children in the highest exposure group were three times more likely to have low-average IQ scores and twice as likely to be 2 years behind in reading comprehension.[49]

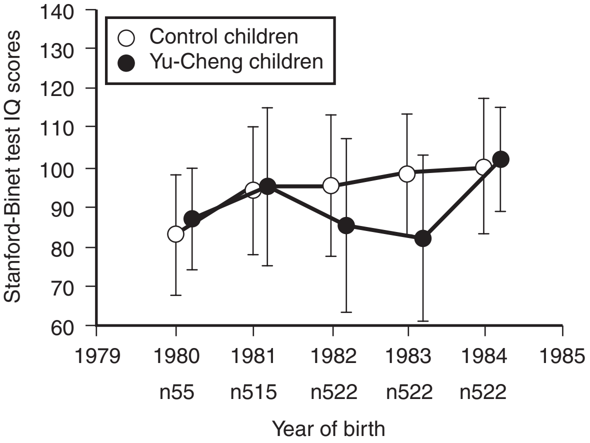


Figure 12–3. Stanford-Binet test IQ scores in 4-year-old children with yu-cheng and children in a control arm by year of birth. Error bars represent 1 standard deviation. The contaminated rice was consumed in 1979. *(From Chen Y-C et al: Cognitive development of yu-cheng ["oil disease"] children prenatally exposed to heat degraded PCBs,* JAMA *268:3216, 1992.)*

LEAD

The major repository for lead is bone, where the turnover rate is approximately 25 to 30 years. Chronic lead exposure results in significant accumulation of lead in the skeleton. During pregnancy, calcium turnover is greatly increased,[55] which may increase mobilization of lead stores from bone.

Lead mobilization was measured in one expectant couple by determining the isotopic ratio (IR) of lead, $^{206}Pb:^{207}Pb$ (Fig. 12-4).[65] The couple had initially lived in England, which has one IR for lead, and subsequently moved to Australia, which has a different IR for lead. If blood lead is primarily derived from air, the IR of blood lead would parallel the IR prevalent in Australia. If blood lead is primarily derived from bone, blood lead IR would not parallel that found in Australia; instead, it would be a reflection of the IR of lead absorbed in England during childhood. The man's blood lead IR paralleled that of Australia, but the woman's did not, indicating a significant source of lead for her other than an environmental one, probably from her skeletal stores. After delivery, her blood lead IR also paralleled that prevalent in Australia.

This hypothesis has been confirmed in two larger studies: one in pregnant Latin American women living in California,[84] and one in pregnant Eastern European women living in Australia.[36] Significant fetal exposure because of an elevated

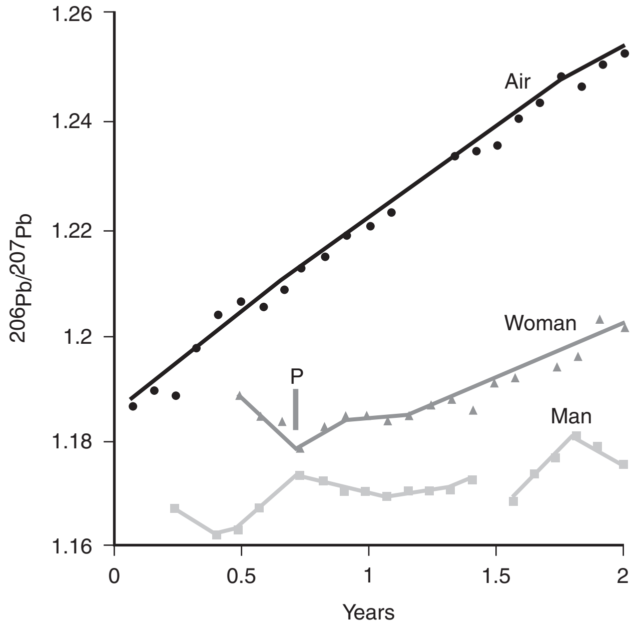

Figure 12–4. Isotopic ratio of airborne lead to blood lead of a man and a peripartum woman in 1974 and 1975. Declining isotopic ratio in the woman's blood before birth indicates a different source of lead from that of the man. Dietary sources of lead were the same. The only different source of lead for the woman is that coming from her skeleton during pregnancy. *P,* time of birth. *(From Manton WI: Total contribution of airborne lead to blood lead,* Br J Ind Med *42:169, 1985.)*

maternal body burden of lead is shown in two case reports of congenitally lead-poisoned children delivered by women inadequately treated for childhood plumbism.[89,95]

MERCURY

The CDC website on biomonitoring shows that approximately 8% of women have body burdens of mercury already exceeding the reference dose for this toxicant and are at risk for bearing children already harmed by mercury.

MATERNAL EXPOSURES CONCURRENT WITH PREGNANCY

Exposures concurrent with pregnancy can come from many sources. Biologic markers of exposure to the fetus are being developed using meconium[4,6,106] and hair.[81]

Occupation

Several occupations have been shown to increase the risk of a poor outcome of pregnancy, and the studies showing that result have been reviewed.[78,88,105] Many studies are inconclusive or difficult to interpret. The strongest associations between workplace exposures and poor reproductive outcome (e.g., spontaneous abortion, miscarriage, and birth defects) have been found for lead, mercury, organic solvents, ethylene oxide, and ionizing radiation. Table 12-2 lists agents that are suspected to cause adverse pregnancy outcomes.[105]

Paraoccupation

Other important sources of exposures to the mother occur through paraoccupational routes. These exposures occur when the father or others bring or track home occupational chemicals, when the home itself is in an occupational setting, or when industrial chemicals are brought home for home use.[68]

Paraoccupational exposure occurred when a janitor in Alamogordo, New Mexico, brought home from a local seed company some grain that was intended for planting only. This grain had been treated with a fungicide containing organic mercury. The janitor used this grain to feed his hogs, one of which was subsequently slaughtered for consumption by the family. Three of nine children in the family became severely ill with organic mercury poisoning.[25,79] The mother also ate the contaminated meat during the second trimester of her pregnancy. Maternal serum and urine had elevated levels of mercury, as did the neonate's urine, indicating placental transfer of the mercury.[23] The newborn had gross tremulous movements of his extremities, which developed into myoclonic convulsions. At 1 year of age he could not sit up, and he was blind. The mother remained symptom-free.

Air

Air is an important source of exposure to the pregnant woman and fetus. Exposure of the mother to environmental tobacco smoke causes decreased birthweight,[37,41,67] an increased risk of sudden infant death syndrome,[24,73] and a predisposition to persistent pulmonary hypertension (Fig. 12-5).[3] In addition, exposure of the mother to fumes of naphthalene has resulted in severe fetal hemolysis in the presence of glucose-6-phosphate dehydrogenase deficiency.[109] Severe fetal hemolysis after maternal naphthalene exposure can occur in the absence of glucose-6-phosphate dehydrogenase deficiency.[70]

Water

Because the embryo and fetus develop through multiple short critical periods, the quality of water consumed by a pregnant woman is a daily concern; a yearly average of contaminants is insufficient to protect the developing fetus. Public and well water supplies can vary greatly over the course of a year.

A review of the relationship of drinking water contaminants to adverse pregnancy outcomes illustrates the risk from exposure to byproducts of chlorinated water disinfectants.[10] These studies show a moderate association between trihalomethane exposure and infants who are small for gestational age, infants with neural tube defects, and spontaneous abortions. Excess neural tube defects, oral clefts, cardiac defects, and choanal atresia were found in studies evaluating trichloroethylene-contaminated drinking water.[10]

Diet

Diet may be an important vehicle for exposure. In Minamata Bay, Japan, methyl mercury from an acetaldehyde-producing plant contaminated the food chain.[40] Pregnant women from a fishing village on the same bay gave birth to severely neurologically damaged infants, whereas they themselves had mild transient paresthesias or no symptoms at all.[66] The safe limit of organic and

Mothers who smoke were identified by history of smoking or by umbilical cord cotinine concentrations greater than 13.7 ng/mL. *Horizontal bars* indicate medians of both groups. Medians were significantly different between the two groups (Mann-Whitney rank sum test: Z = 2.78941; *P* = .0053). *(From Bearer CF et al: Maternal tobacco smoke exposure and persistent pulmonary hypertension of the newborn,* Environ Health Perspect *105:205, 1997.)*

inorganic mercury ingestion for pregnant women is the subject of much discussion and ongoing research.[63,104] The U.S. Environmental Protection Agency (EPA) has set the reference dose of mercury at 0.1 µg/kg/day. The concern over mercury exposure from vaccination arose based on this new reference dose.

PATHWAYS OF FETAL EXPOSURE

Placenta-Dependent Pathways

Two possible routes of fetal exposure to environmental hazards are placenta-dependent pathways and placenta-independent pathways (Box 12-1). For a placenta-dependent chemical to reach the fetus, it must first enter the mother's bloodstream and then cross the placenta in significant amounts. Not all environmental toxins meet these criteria; asbestos and radon gas do not meet these criteria unless they have been ingested.

BOX 12–1 Pathways of Fetal Exposure

PLACENTA-DEPENDENT PATHWAYS
Small molecular weight: carbon monoxide
Lipophilic: benzo[a]pyrene, ethanol
Specific transport mechanism: lead

PLACENTA-INDEPENDENT PATHWAYS
Ionizing radiation
Heat
Noise
Electromagnetic fields

Three properties that enable chemicals to cross the placenta are low molecular weight, fat solubility, and resemblance to nutrients that are specifically transported. A low-molecular-weight compound is carbon monoxide, a constituent of environmental tobacco smoke. Carbon monoxide is an asphyxiant because it displaces oxygen from hemoglobin, forming carboxyhemoglobin. If enough carboxyhemoglobin accumulates in the circulation, cellular metabolism is impaired because oxygen transport, delivery, and use are inhibited. Fetal carboxyhemoglobin accumulates more slowly than maternal carboxyhemoglobin, but it increases to an equilibrium approximately 10% greater than in the maternal circulation.[44,61] Nonfatal carbon monoxide poisoning of the mother may prove to be fatal to the fetus.[30]

Examples of fat-soluble chemicals that readily cross the placenta are solvents and polycyclic hydrocarbons (benzo[a]pyrene, a carcinogen in environmental tobacco smoke, is a polycyclic hydrocarbon). Ethanol, a type of solvent, causes fetal alcohol syndrome (see Chapter 38, Part 2). In pregnant ewes, intravenous infusion of ethanol results in identical maternal and fetal blood alcohol levels.[19] PCBs have been measured in equal concentrations in fetal and maternal blood.[13]

Calcium is a nutrient that is actively transported across the placenta to provide the fetus with 100 to 140 mg/kg per day during the third trimester (see Chapter 49, Part 2).[92] Lead is believed to be transported by the calcium transporter. The fetal blood lead concentration is equivalent to the maternal blood lead concentration.[35] More recent animal studies have shown that calcium supplementation may reduce the transfer of lead from prepregnancy maternal exposures to the fetus.[39]

Placenta-Independent Pathways

Placenta-independent hazards to the fetus include ionizing radiation, heat, noise, and, possibly, electromagnetic fields.

RADIATION

Ionizing radiation is a well-characterized teratogen. Much of our knowledge comes from studies of the survivors of the atomic bombs in Hiroshima and Nagasaki. Children exposed in utero at less than 18 weeks' gestation showed a dose response of increasing microcephaly with increasing dose of radiation. The lowest observable effect occurred at a dose of 1 to 9 rad (Fig. 12-6).[8]

In comparison, the brain of a neonate undergoing cranial computed tomography (CT) with settings of 400 mA, 125 kV (peak), and a standard slice thickness of 4 mm receives a dose of 10.5 rad.[107] Because this level is close to that resulting in microcephaly, it has been recommended that CT be used sparingly for premature infants, particularly when other imaging techniques are available.[22] An excess of cancer among Japanese individuals exposed in utero has also been reported (Fig. 12-7).[112]

Not all forms of radiation are hazardous to the fetus. Ultraviolet light does not penetrate to the fetus and does not constitute a future cancer risk.

HEAT

Heat may directly penetrate to the fetus and cause birth defects. In a study of the effects of heat on the outcome of pregnancy, 22,491 women undergoing α-fetoprotein screening were asked

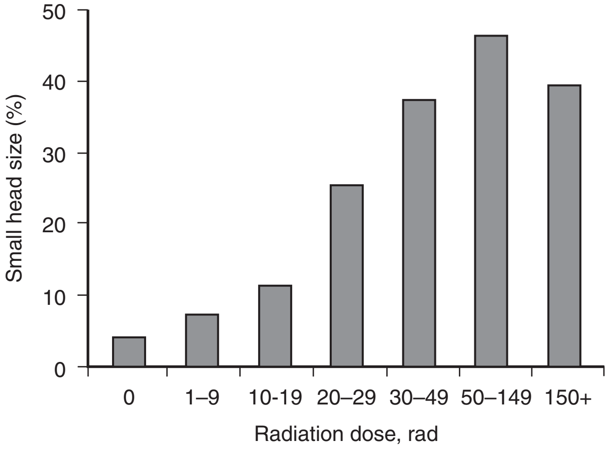

Figure 12–6. Percentage of Hiroshima children with head circumference 2 or more standard deviations below average, by fetal dose. Exposure occurred before 18 weeks of gestation. *(From Blot WJ: Growth and development following prenatal and childhood exposure to atomic radiation,* J Radiat Res [Tokyo] *16[suppl]:82, 1975.)*

about their use of hot tubs, saunas, and electric blankets, and whether they had experienced a fever during the first trimester.[69] The adjusted relative risk for neural tube defects with hot tub use was 2.8 (95% CI 1.2-6.5). With exposure to two of these heat sources, the relative risk increased to 6.5.

NOISE

Noise has a waveform that may be transmitted to the fetus (see Chapter 30, Part 2), and noise has been associated with certain birth defects, prematurity, and low birthweight.[23] In addition, noise-induced hearing loss may be evident after in utero exposure. In a study of 131 infants whose mothers worked in noisy conditions and received a noise dose of 65 to 95 LAeq.9m (dB) (a unit of noise dose calculated by an international standard and averaged over the 9 months of pregnancy), there was a threefold increase in the risk of a high-frequency hearing loss among infants whose mothers had received the highest doses of noise (Table 12-3).[57]

TABLE 12–3 Comparisons of Percentages of Children with Hearing Loss at 4000 Hz* between Classes of Noise Exposure during Fetal Life

NEONATAL INTENSIVE CARE UNIT

A unique source of exposure to the fetus occurs if the fetus is born prematurely. Premature infants in the neonatal intensive care unit have several types of exposure in this highly artificial setting, including plasticizers,[80] noise,[7] electromagnetic fields,[2] and lead.[5] This subject has been discussed in several articles and is not reviewed here.[11]

FETAL PHARMACOKINETICS

Fetal Distribution

The distribution of chemicals in the fetus differs from that in the adult (see Chapter 38, Part 1). Because there is reduced protein binding in the fetus as a result of relative hypoproteinemia, chemicals can diffuse into tissues more readily. The blood-brain barrier is immature; chemicals can reach the brain easily. There is little or no body fat until approximately 29 weeks of gestation. Before that time, chemicals that normally accumulate in fat accumulate in other fat-containing tissues, especially the brain. An example of this redistribution is shown in Figure 12-8.[29]

DDT (an organochlorine pesticide, dichlorodiphenyltrichloroethane) was administered orally to mice at various ages that correspond to the human brain growth spurt. The amount of radioactivity was measured in brain tissue after 24 hours and again after 7 days. There were striking differences in the initial amount of DDT accumulated and the retention of DDT after 1 week. At 24 hours, 20-day-old mice accumulated more DDT in their brains than mice at other ages. The DDT persisted longest, however, in the animals given DDT at 10 days of age. In subsequent experiments, the mice treated at 10 days seemed to have more behavioral abnormalities than mice treated on either day 3 or day 19 of life, suggesting that the persistence of the pesticide was more important than the initial accumulation in regard to toxic effects. These results reflect the complexities of chemical distribution in the fetus as many organ systems continue to develop and mature.

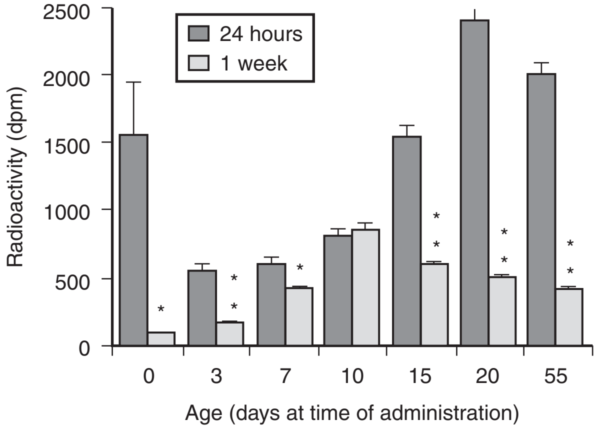

Figure 12–8. Radioactivity levels (in disintegrations per minute [dpm]) in mouse brain 24 hours and 1 week after oral administration of 1.48 MBq [^{14}C]DDT (dichlorodiphenyltrichloroethane) per kg of body weight. Height of bars represents mean ± standard deviation; statistical difference between 24 hours and 1 week is indicated by $P < .01$ (*single asterisk*) and $P < .001$ (*double asterisk*). (*From Eriksson P: Age-dependent retention of [^{14}C]DDT in the brain of the postnatal mouse,* Toxicol Lett *22:326, 1984.)*

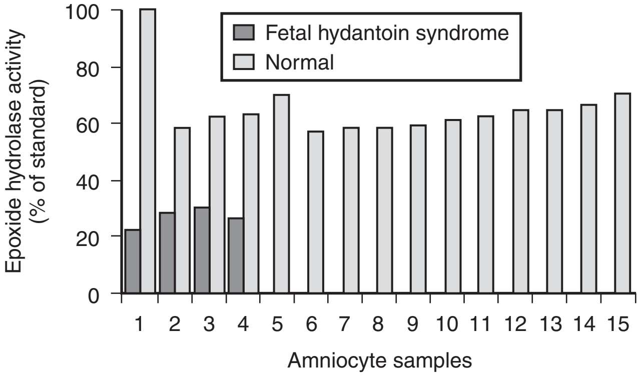

Figure 12–9. Epoxide hydrolase activity in amniocyte samples from 19 prospectively monitored fetuses. Samples from four fetuses subsequently given a diagnosis of fetal hydantoin syndrome are indicated by *black bars*. Samples from 15 fetuses subsequently confirmed not to have characteristic features of the syndrome are indicated by *hatched bars*. (*From Beuhler BA et al: Prenatal prediction of risk of the fetal hydantoin syndrome,* N Engl J Med *322:1570, 1990.)*

Fetal Metabolism

Chemicals are metabolized by a wide variety of enzymes, which differ among individuals by genetic polymorphisms and by gestational age. Ecogenetics is the study of genetic predisposition to the toxic effects of chemicals.[41] An example of fetal ecogenetics is the susceptibility of some fetuses to the development of fetal hydantoin syndrome with in utero exposure to phenytoin. Buehler and coworkers[12] prospectively monitored 19 women receiving phenytoin during their pregnancy. Epoxide hydrolase, an enzyme important in the metabolism of phenytoin, was measured in amniocytes from these pregnancies. Four of the samples had less than 30% of the standard activity (Fig. 12-9). All four infants corresponding to these samples had features of fetal hydantoin syndrome; their genetic background made them susceptible to an environmental exposure.

The expression of many proteins, including enzymes that metabolize xenobiotics, changes with gestational age. The developmental expression of alcohol dehydrogenase in the guinea pig is shown in Figure 12-10.[15] Activity in the fetal liver is two orders of magnitude less than in the maternal liver. Even at 2 days of age, the difference in activity is still at one order of magnitude; environmental and occupational chemicals might not be cleared from the fetal compartment as rapidly as from the mother.

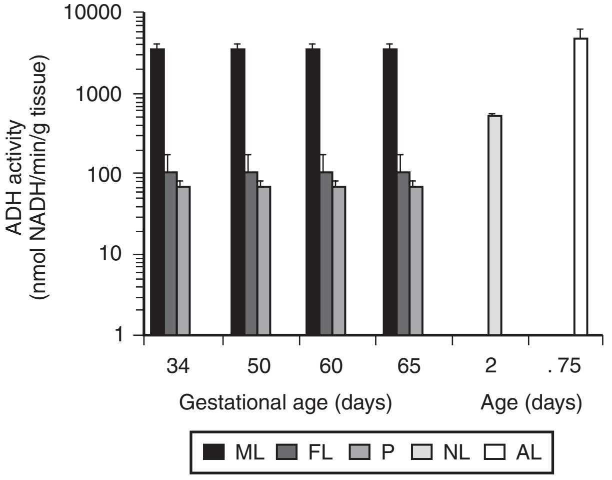

Figure 12–10. Activity of alcohol dehydrogenase (ADH) in guinea pig maternal liver (ML), fetal liver (FL), placenta (P), neonatal liver (NL), and adult liver (AL). Data are presented as mean ± standard deviation ($n = 6$ at 34 days' gestation, $n = 5$ at 50 days' gestation, $n = 6$ at 60 days' gestation, $n = 6$ at 65 days' gestation, $n = 5$ at 2 postnatal days, and $n = 8$ at >75 postnatal days). (*From Card SE et al: Ontogeny of the activity of alcohol dehydrogenase and aldehyde dehydrogenase in the liver and placenta of the guinea pig,* Biochem Pharm *38:2535, 1989.)*

The fetus may be protected against toxic effects if the active form of a chemical is its metabolite. An example of such a chemical is acetaminophen, the most common drug used in suicide attempts during pregnancy. Acetaminophen is metabolized by the P-450 cytochrome system to hepatotoxic and nontoxic intermediates.[91] The expression of the P-450 enzymes is highly regulated developmentally and by induction. Because many of these enzymes are poorly expressed in fetal tissues, the fetus may be protected from the effects of high doses of acetaminophen. In four case reports, the liver enzymes of neonates who were delivered on an emergency basis to overdosed women were normal or minimally elevated in the presence of severe maternal hepatotoxicity.[14,56,83,93]

SPECTRUM OF OUTCOMES

Because of the complexity of development and of developmental processes from the fertilized egg to the newborn infant, sites of action of chemicals and radiation are numerous. An intrauterine exposure to radiation or chemicals may result in a broad array of phenotypic effects. Box 12-2 lists some of the phenotypes.

Major malformations surpassed low birthweight and respiratory distress syndrome as the leading causes of infant death in 2002.[53] The rates for the top three causes of infant death per 100,000 live births were (1) congenital malformations, deformations, and chromosomal abnormalities, 140.7; (2) disorders relating to short gestation and low birthweight, not elsewhere classified, 114.4; and (3) sudden infant death syndrome, 50.6. All three have been associated with environmental exposures as discussed in this chapter.

BOX 12–2 Spectrum of Phenotypic Effects

- Preterm birth
- Growth restriction
- Microcephaly
- Major and minor malformations
- Deformations
- Metabolic dysfunction
- Cognitive dysfunction
- Behavioral dysfunction
- Malignancy

Further evidence has linked the environment to birth defects. A study of 371,933 women investigated the relative risk of an infant being born with a birth defect similar to the birth defect affecting a preceding sibling (Table 12-4).[60] The relative risk of a similar birth defect was 11.6 (95% CI 9.3 to 14.0), and it decreased by more than 50% when the mother changed her living environment between the two pregnancies.

Reproductive dysfunction may also be a manifestation of occupational and environmental exposures. When hamsters are exposed in utero to phenobarbital, they exhibit altered neonatal behavior and reproductive maturation.[9] In studies of a cohort of adolescents exposed in utero to phenobarbital as part of a study to reduce postnatal hyperbilirubinemia, long-term effects, including lower testicular volume of exposed boys, were evident.[110] Dioxin and similar compounds have been shown to alter male reproductive function in wildlife.[20] Scientific debate continues over whether these observations in wildlife apply to humans.

Permanent metabolic dysfunction has been associated with prenatal and neonatal exposure to monosodium glutamate (MSG) in animals. In female rats exposed neonatally to MSG, circulating growth hormone was reduced by 75% to 85%, and animals were mildly obese.[76] In addition, levels of a female-specific cytochrome P-450 were increased by almost 100%. In male rats, neonatal exposure to MSG permanently blocked growth hormone secretion and resulted in stunted body growth, obesity, and impaired drug metabolism.[90] There was irreversible suppression of cytochrome P-450 2C11. These effects have now been linked to increased apoptosis in

TABLE 12–4 Risk of Similar and Dissimilar Birth Defects in Second Infants of Mothers with an Affected First Infant

		SECOND INFANT					
		SIMILAR DEFECT			DISSIMILAR DEFECT

[*] Numbers in parentheses are 95% confidence intervals for the odds ratios.

[†] Asymptotic confidence interval (numbers are too large for exact calculation).

[‡] Includes all 23 categories of isolated defects and the category of multiple defects. In addition to those listed, the categories were anencephaly; spina bifida; hydrocephalus; other; central nervous system defects; eye defects; ear, face, or neck defects; circulatory system defect; respiratory system defect; esophageal defect; abdominal wall defects; anal defect; renal defects, axial defects; skin, hair, or nail defect; or birth defect: Down syndrome and other chromosomal syndromes.

From Lie RT et al: A population-based study of the risk of recurrence of birth defects, *N Engl J Med* 331:14, 1994.

the developing brains of animals exposed to glutamate.[74] As a result of these observations in animals, MSG was removed from baby foods in 1969. The effects of phenobarbital and MSG have been called *delayed teratogenic expression* because the effects of the exposure are not immediately apparent at birth.

Developmental neurotoxicity warrants special mention. The development of the central nervous system requires expression of unique proteins in specific cell populations within specific critical windows of time. Injury to these populations may result in neurodevelopmental disorders, such as mental retardation, autism, dyslexia, and attention-deficit/hyperactivity disorder.

It is estimated that 3% to 8% of the 4 million children born each year in the United States are affected by a neurodevelopmental disability.[103] Some disabilities are caused by genetic aberrations (Down syndrome, fragile X syndrome), some are caused by perinatal anoxia or meningitis, and some are caused by exposure to drugs of abuse (ethanol, cocaine). The cause of most neurodevelopmental disabilities is unknown, however. Environmental chemicals, such as lead, PCBs, and mercury, are known developmental neurotoxins.

Of the 3000 chemicals produced or imported at more than 1 million lb a year, 43% have not received even minimal toxicologic assessment, and only 22% have been tested to determine whether they have the potential to cause developmental damage.[34] As of 1998, of all chemicals regulated by the EPA, only 12 have had any developmental neurotoxicity testing.[100] It remains a real possibility that neurodevelopmental disabilities arising in the newborn period are a result of in utero chemical exposure.

CONCLUSION

This chapter has described the many different sources of exposure and the timing of exposure to occupational and environmental chemicals. The complexity of maternal-fetal pharmacokinetics has been outlined, and many of the various types of outcomes have been discussed. The science of environmental medicine continues to evolve, elucidating sources of potential harm. What can one do now with the limited information available?

First, women who work have a right by law to be informed about the chemicals they work with,[77] and they have a right by law to be protected from harmful exposures. Materials safety data sheets should be available to any employee who requests them. These sheets supply information about potential reproductive effects. Personal protective gear should be available, and increased monitoring of potential exposures should be instituted. In certain instances, temporary job shifting may prevent potential exposure.

More insidious are the exposures that occur outside the workplace, which are often unknown to the individual exposed. Sources of exposure include the chemicals and radiation in the environment—in water, food, and air. Current regulations rarely consider the unique susceptibilities and vulnerabilities of unborn children. Efforts should be made to inform the public and the legislature about these potential toxins so that safeguards to children's health may be devised.

It is very challenging for the neonatologist confronted with a neonate who has a problem resulting from an environmental exposure to determine the cause of that problem. Confirming the etiologic agent is almost impossible and requires several steps. First, a detailed exposure history is vital. Guidelines for taking this history can be found in a monograph from the U.S. Department of Health and Human Services, Agency for Toxic Substances and Disease Registry (ATSDR), *Case Studies in Environmental Medicine: Taking an Exposure History* (see Carter and coworkers in Additional Reading).

It is not enough to know the mother's occupation. One must ascertain exactly what she does at work, what the father does at work, what their hobbies are, what they do at home, what type of residence they have, and what type of neighborhood they live in. What is the composition of their diet? Do they smoke or use alcohol or other types of recreational drugs? Were medicines (prescribed and over-the-counter) used during the pregnancy? One must also be aware that taking this history has the potential for raising guilt feelings in the parents, and one must be prepared to address this issue.

When the history of exposure has been taken, one must gauge the amount of exposure. An industrial hygienist might be able to make an estimate, but such an estimate is expensive and time-consuming. For certain types of exposure, biomarkers may be confirmatory. Examples are cord blood concentrations of cotinine for prenatal exposure to the products of tobacco smoke and urinary concentrations of mercury for mercury exposure.

Second, one must ascertain whether a neonate's particular problem is known to occur with a given type of exposure. Appendices for computerized databases are listed in the ATSDR monograph, and birth defect information services are available online at www.otispregnancy.org/.

Third, when an association is made between an exposure and an adverse outcome, one must determine the likelihood that the exposure caused the adverse outcome. This assessment should be carried out with the help of the teratology hotline (www.otispregnancy. org) and any additional resources available (e.g., dysmorphologist, neuropsychologist). Methylethylketone, a commonly used solvent, has been shown to cause an increase in major malformations and intrauterine growth restriction in rats[27,86,87] and mice.[84] In addition, human epidemiologic studies have shown an association between organic solvent exposure (in human studies one rarely finds exposure to only one organic solvent) and malformations.[45,51,75] It is reasonable to conclude that microcephaly and mental retardation observed in a child delivered to a woman exposed to methylethylketone during her pregnancy are a result of this exposure.

More formal criteria for assessing causation have been reviewed by Scialli.[88] What the mother should do to prevent a recurrence is a complicated issue. If the exposure is job related, job discrimination may result.[77] It may be necessary for the patient and her physician to work with the employer to find a suitable (and legal) alternative. Sometimes simple hygienic measures, such as changing contaminated clothing at work or frequent hand washing, are the only requirements. Additional interventions may be the use of personal protective equipment and temporary job rotation to a position in which exposure does not occur.

The hotlines for teratology information are part of the Organization of Teratology Information Services and are listed online at www.otispregnancy.org. *Case Studies in Environmental*

CHAPTER 13

Developmental Origins of Adult Health and Disease

Sherin U. Devaskar and Kara Calkins

FETAL ORIGINS OF ADULT DISEASE CONCEPT

The concept of fetal origins of adult disease popularized by Barker arose from a robust association between small size at birth and the risk of chronic adult diseases, such as coronary artery disease, hypertension, stroke, type 2 diabetes mellitus, and osteoporosis.[6,7,19] These original epidemiologic observations have been extensively replicated by multiple groups in varying populations of different ethnicity employing birthweight as a surrogate for the intrauterine state.[52,53] During the 1944-1945 Dutch famine, women who were previously adequately nourished were subjected to low caloric intake and the associated environmental stressors. The offspring that were conceived or were gestating in their mothers' wombs during the famine as adult survivors at age 50 to 60 years showed a higher incidence of hypertension, cardiovascular-related mortality and morbidity, and glucose intolerance/insulin resistance.[85] The culmination of all these epidemiologic associations is referred to as the "Barker hypothesis."

Although fetal growth and birthweight have served as surrogate markers of fetal nutrition and health, it is clear that fetuses subjected to nutritional perturbations with no resultant change in size or growth also develop adult chronic diseases.[30,64] These observations support adaptations in a nutritionally adverse in utero environment targeted at immediate survival, which may or may not interfere with fetal growth depending on the severity of the adversity.[30] Malnutrition during gestation that includes macronutrients or micronutrients can potentially set the stage for adult-onset chronic diseases.[110,111] Although nutritional deficiency is considered to exist only in developing countries, differential socioeconomic status with varying access to health care and sociocultural and ethnic differences resulting in disparities are rampant in the Western world, including the United States.[53] These situations can lead to malnutrition in macronutrients and micronutrients, which translates into an altered phenotype of this subpopulation.

As more investigations in human and animal models are unfolding, various mechanisms responsible for this fetal-to-adult association are being unraveled. These adaptive mechanisms combat an adverse nutritional or metabolic intrauterine environment by developing safeguards for the energy supply sometimes at the expense of growth, ensuring a reduced fetal demand. These adaptations generate a "thrifty phenotype."[36] After birth, these same adaptive systems remain masked, however, without much contribution to health or disease.[30,64] Additional nutritional or metabolic stressors encountered subsequently tip the finely crafted phenotypic balance toward a disease state.[30,32] The conventional belief is that these phenotypic features are expressed mainly in aging adults.[6,7] Given lifestyle changes toward an increased caloric intake and relative inactivity, however, some of these features are seen in childhood or during late teenage years.[15]

At the other extreme, an infant of a diabetic mother who is large for gestational age (LGA) develops obesity and type 2 diabetes during late childhood.[13] This condition then leads to associated hypertension and vascular complications.[57] More recently, lean adult offsprings of diabetic mothers were also observed to develop skeletal muscle insulin resistance, a forerunner of type 2 diabetes mellitus.[83] Although birthweight at both ends of the spectrum is associated with adult chronic diseases, birthweight is only a presenting feature. Even in the absence of a change in birthweight, any compromise to the fetus, in the form of malnutrition; reduced blood flow; hypoxia; or other stressors such as drug exposure, toxins, infections, and inflammation, which has the propensity of perturbing the fetal hormonal-metabolic milieu, can set the stage for the subsequent onset of chronic diseases.

Although multiple investigations have employed growth as a surrogate for nutrition, these are two distinct processes. Nutritional derangement could ultimately affect growth as a protective mechanism targeted at saving the restricted energy supply for vital organs. Growth can suffer in the presence of adequate nutrition because of multifactorial etiologies. Evidence is accumulating that nutritional deficiencies that do not affect the growth potential can also have far-reaching consequences on the adult phenotype. This situation is encountered in the case of isolated glucose deficiency, certain essential amino acid deficiencies, and micronutrient deficiencies in the fetus that are associated with cardiovascular and metabolic disturbances during adult life.[11,28,84] Additional investigations more recently have shown the influence of the early embryonic and postnatal stages in creating (embryonic stage) or modulating (postnatal stage) the phenotype of an individual.

INFLUENCES ON THE EARLY EMBRYO

In vitro exposure of embryos in early preimplantation stage revealed an effect of nutrients in the culture media on the subsequent phenotype of the offspring.[42] In vitro fertilization resulting in singleton pregnancies led to taller girls with altered insulin-like growth factor (IGF) to the corresponding binding protein ratios.[66] There is growing evidence that artificial reproductive technology with resultant multiple pregnancies lends itself to an increased incidence of infants with growth restriction or premature infants.[42] There is a higher incidence of disorders consistent with parental imprinting. Examples include Beckwith-Wiedemann, Angelman, and Prader-Willi syndromes.[42] In pregnancy, imprinted genes play a role in determining the placental size and fetal growth.[42] Most paternally expressed genes enhance placental and fetal growth, whereas most maternally expressed genes reduce placental and fetal size.[42] Examples consist of paternally expressed IGF-II and maternally expressed IGF-II receptor.[74] In addition, maternal and placental health that modifies fetal blood flow or nutrient (macronutrients and micronutrients) supply including oxygen delivery can alter the fetal growth potential with far-reaching consequences.[21] Imprinting of genes that predetermine the growth potential of the fetus may be a result of the in vitro culturing conditions or the subfertile nature of the gametes employed in the in vitro fertilization process.[74]

POSTNATAL AND EARLY CHILDHOOD GROWTH

The first indication that postnatal stages of development can influence the long-term outcome related to perturbed fetal nutrition came from the observations during the Leningrad siege.[92] Exposure in utero and postnatally to nutritional deprivation failed to produce signs of chronic diseases in adults.[92] These findings suggested that postnatal manipulation of nutrition may have a protective effect on the trajectory of fetal origins of adult disease. More recent investigations have revealed that in girls and boys, low birthweight with a slow growth pattern between 0 and 2 years followed by exponential growth between 2 and 8 years led to increased mortality secondary to cardiovascular events, and an increase in glucose intolerance and type 2 diabetes mellitus.[8] These studies established that postnatal growth patterns also were important in predetermining the adult phenotype. These findings are of particular interest to neonatology, where there continues to be an ongoing dilemma as to what is ideal postnatal growth, and whether this growth rate should be the same for infants of varying birthweight ranges and differing presentations.

Infants who are small for gestational age (SGA) have an increased risk of adult short stature (i.e., 5.2% of infants with low birthweight and 7.1% of infants with low birth length are at risk). In contrast, 80% of infants who are SGA achieve a height in the normal range by 6 months of age.[15] Metabolic and endocrine changes in infants who are SGA include reduced insulin sensitivity, lipid profile aberrations, premature adrenarche, and polycystic ovarian syndrome.[15] Most of the phenotypic changes seem to be due to insulin resistance, although the site of insulin resistance seems to be an imbalance between hepatic insulin resistance and pancreatic β-islet cell production of insulin.[103]

Four-year-old children who were SGA already have a noticeable reduction in muscle mass with a smaller increase in fat mass compared with children who had normal birthweight.[76] The reduction of insulin sensitivity is magnified with fat mass deposition and a faster "catch-up" growth pattern, which is associated with disease attributable to insulin resistance. This early growth during childhood that is sustained through adolescence predetermines who goes on to develop type 2 diabetes mellitus as an adult. Similarly, infants who are SGA go on to develop overt dyslipidemia during adulthood. Metabolic syndrome (defined by increased risk for developing heart disease, stroke, or diabetes) is evident in 2.3% of young adults who were SGA compared with 0.4% of young adults who had normal birthweight.[15] In addition to metabolic syndrome, girls who were SGA develop premature pubarche and polycystic ovarian syndrome.[41,82] More recently, investigations have uncovered an association of type 2 diabetic risk alleles in infants born with a reduced size, linking the genetics of type 2 diabetes with low birthweight as well.[27,63] It is important to distinguish between SGA (size) and intrauterine growth restriction (IUGR) (growth); the latter reflects intrauterine compromise.

Twins generally have lower birthweights than singletons, and an expected outcome would be a higher incidence of adult-onset chronic diseases in twins.[78] Epidemiologic studies reveal no increase of adult disease in the twin population, however. In large studies, the inverse association of birthweight with the eventual development of type 2 diabetes mellitus is preserved even in twins.[79] The smaller of the twin pair has a higher chance of developing chronic diseases as an adult. It was observed that every 1-kg decline in birthweight led to doubling the risk of developing diabetes in this Swedish twin cohort.[68]

Premature infants, particularly infants with very low birthweight (VLBW) (<1500 g birthweight), although distinctly different in presentation at birth, tend to mimic infants with IUGR in the final phenotype. This similarity may be related to the nutritional compromise and stressors encountered during the early postnatal phase of life. The clinical practice of providing relatively low protein and high carbohydrate in total parenteral nutrition (uncommon today) to meet the estimated calorie requirement of these infants may prove to be a contributor. In addition, other stressors that invoke endogenous glucocorticoid surges and intermittent exposure to hypoxia all may play a role in "programming" these infants.[87]

After the early postnatal period when complete oral feedings are established, a significant catch-up growth phenomenon is realized in most infants with increasing caloric provision. Long-term follow-up investigations of infants with VLBW reveal a higher systolic blood pressure, central adiposity by 19 years of age, and emergence of premature pubarche in 24% of these children.[15,40] This presentation in infants with VLBW is reminiscent of what was encountered in infants with IUGR who faced an adverse in utero environment. In both cases, the postnatal catch-up growth leads to disease presentations secondary to insulin resistance. An investigation involving 18- to 27-year-old adults born premature with a birthweight less than 1500 g showed hyperinsulinemia and glucose intolerance, hypertension, and hypertriglyceridemia, paving the path to metabolic syndrome.[40]

CATCH-UP GROWTH

The phenomenon of postnatal catch-up growth seems to reflect intrauterine or early postnatal nutritional deprivation. It is a normal tendency by the body to compensate after a nutritionally restricted period, showing rapid growth. This rapid growth targets short-term benefits, which include survival and protecting the reproductive capacity.[44] It is evident, however, that catch-up growth tends to favor nutrient deposition in white adipose tissue resulting in adiposity, particularly visceral adiposity; a rearrangement of skeletal muscle mitochondria; and increased oxidative injury.[88] These changes set the stage for metabolic syndrome, diabetes mellitus, and coronary artery disease as the child matures into an adult.[6,7,35] This catch-up growth results in a shortened life span with changes in the telomeric length.[17] For “short-term gain,” catch-up growth results in “long-term pain.”

The question arises, should postnatal catch-up growth not be fostered? If postnatal nutrition matches intrauterine nutrition, can adult chronic diseases be curbed and result in longevity? Although animal studies lend credence to this concept, the absence of catch-up growth, while resulting in glucose tolerance, lean body composition, and reduced coronary artery disease with longevity, may negatively affect cognition and reproductive capacity.[44,96] Rapid postnatal growth, whether superimposed on LBW or normal birthweight, seems to have a similar effect in producing adult chronic diseases.[8] Avoidance of rapid postnatal catch-up growth within a short period may be beneficial if replaced with moderate long-term growth.

At the other end of the spectrum, infants born with a heavier birthweight, resulting from either maternal diabetes or obesity, are also prone to adult chronic diseases. These infants are obese during childhood and develop insulin resistance with the associated phenotypic presentations.[13,25] Investigations in infants who are LGA show that postnatal intervention consisting of breast feeding versus bottle feeding led to a decline in obesity during childhood.[10] This intervention represents a “catch-down” mechanism at work. There is a J-shaped correlation curve, when birthweight is associated with the various chronic disorders of adulthood.

When promotion of prolonged and exclusive breast feeding was the intervention in 17,046 infants who were not necessarily LGA at birth, no such prevention of overweight or obesity at 6.5 years of age was observed in a population from Belarus, where the obesity prevalence in children is quite low compared with the United States.[51] In contrast, infants who are LGA also express elevated IGF concentrations predisposing them to dysregulated cell proliferation and the subsequent development of cancer. One can speculate that these infants experience catch-up growth during fetal life after experiencing slow growth during the early embryonic phase.[104] The early slow growth is perhaps related to the inheritance of mitochondrial aberrations from the diabetic mother,[104] and the later presentation as infants with LGA may be due to excessive placental transfer of nutrients. Further postnatal escalated growth leads to earlier acquisition of adult chronic diseases and the associated complications. The weight status in the first 6 months of life predicts obesity at 3 years of age (Fig. 13-1).[93]

MISMATCH CONCEPT

Investigations have solidified the concept of profound effects resulting from a “mismatch” between the early developmental environment and the subsequent environment after birth into childhood and adult life. The degree of mismatch can be increased by deprived environmental conditions during a critical phase of development (prenatal or postnatal) or an excess later or both. Compromised maternal health, nutrition, toxins, stressors, infections, and inflammation can contribute to the former, whereas energy-dense foods and television watching with reduced physical activity can contribute via the latter pathway exaggerating the mismatch further. Such a phenomenon has considerable significance to developing societies that are undergoing rapid socioeconomic transitions or to immigrant families in Western countries that came from developing countries.[32]

Most important to neonatal intensive care units are the neonatal health concerns of nutrition, toxins, stressors, hypoxia, infections, and inflammation during the early phase of life that can have similar effects on the life course of a particular individual. Thought should be exercised before introducing interventions during this period of development that have the potential of altering the life course. The concept of catch-up growth should be reevaluated to determine what is optimal for every subset of the population. At both ends of the spectrum—infants who are LGA and infants with IUGR, who are SGA, or who are premature—there is a period of deprivation followed by exposure to excess. In the case of the former, this deprivation usually occurs during the first trimester with rapid catch-up growth observed during the third trimester resulting in an infant who is LGA, whereas in the latter category, the deprivation is generally in the third trimester with rapid catch-up growth postnatally, as in infants with IUGR and some infants who are SGA. In premature infants who have VLBW, the deprivation is in early postnatal life followed by catch-up growth during the postneonatal stage of development (see Chapter 14).

Although considerable emphasis in most studies has rested on the prenatal or postnatal growth pattern and size at birth or infancy, a perturbation in growth and size is evidence that adaptations are in place to conserve energy at the expense of growth. Situations of deprivation or exposure to stressors can occur, however, in the absence of any effect on the growth potential or size, making it difficult sometimes to understand the mismatch concept and its role in the growing incidence of chronic adult diseases. The developmental origins of adult health and diseases are now recognized to have major public health implications worldwide. The World

Health Organization states, "The global burden of death, disability and loss of human capital as a result of impaired fetal development is huge and affects both developed and developing countries" (www.who.int/int/nutrition/topics/fetal_dev_report_EN.pdf). This statement advocates for a broader concept of maternal well-being and achieving an optimal environment for the fetus (and newborn) to maximize the potential for a full and healthy life. This concept has widened to include plasticity during childhood as is being presently investigated in prospective studies consisting of large populations (Fig. 13-2).

PATHOPHYSIOLOGY

These epidemiologic associations have sparked great interest in determining the pathophysiology behind the link of events that spread over a whole lifetime. To this end, multiple animal models have been developed including acute interruption of uteroplacental-fetal blood flow, global or selective nutrient restriction, and the prenatal introduction of key hormones such as glucocorticoids or sex steroids, with the end result being LBW.[21] Most of these studies were done in rodents, which bear a litter, yielding to some intralitter variability in the adult outcome. Despite this limitation, several investigators began showing multiorgan aberrations owing to an adverse intrauterine environment.

The critical window of development that offers some plasticity (or pluripotency) may vary from organ to organ with differing effects, depending on when the insult occurs and the stage of development for a particular organ. An adverse environment causes an adaptation during this critical window to match the in utero demand to available energy supply as previously stated.[32] This adaptive process consists of alterations in chromatin, gene expression, and cell cycle, all altering the cellular size or shape contributing to the ultimate phenotype. A compilation of these studies has shown aberrations in most organs, including muscle, heart, liver, fat, bone, kidneys, vasculature, lungs, endocrine system, and brain.[4,49,59,71,72,90,103,108] In addition, there is a perturbed metabolic-hormonal-immune response, which alters insulin secretion and signaling pathway, the IGF system, cytokines, other hormonal and receptor pathways, and the hypothalamic-pituitary-adrenal axis.[16,18,24,61,90,95] These aberrations lend themselves to maladaptation when the adverse environment no longer exists. This phenomenon exemplifies the gene-environment interaction.

Investigations have revealed that altered cell proliferation in pancreatic β-islet cells underlies the burnout of these cells, which, along with peripheral tissue adaptations, results in glucose intolerance and diabetes mellitus in adults who had IUGR.[71,89,90] This metabolic change causes dyslipidemia, hepatic cholestasis, and hepatic dysfunction.[28] Changes in myocardial function and vascular reactivity induce changes in blood pressure.[97] Structural aberrations in the kidney related to a smaller size and a reduced number of nephrons also contribute toward hypertension and renal dysfunction that develops with aging.[108] Hypertension, myocardial dysfunction, and dyslipidemia set the stage for coronary artery disease and stroke.[50]

Similar to this pathophysiology, bone health that is impaired during development has long-term consequences related to the development of osteoporosis later in life.[19] In addition, stress-induced changes in neuronal structure

Figure 13–2. Schematic representation of the mismatch concept that emphasizes the degree of disparity between the environment experienced during development, and that experienced later *(hatched line on top)*, on the risk of disease. During the period of developmental plasticity in prenatal and early postnatal life, epigenetic processes are thought to alter gene expression to produce phenotypic attributes best suited to the environment and based on environmental cues transmitted via the mother *(shaded area)*. Greater mismatch gives greater risk of disease from unpredicted excessive richness (high calorie density food, sedentary lifestyle) in the environment. Risk is greater with poorer developmental environment (*A* versus *B*), and with socioeconomic transitions to an affluent Western lifestyle. *(From Godfrey KM et al: Epigenetic mechanisms and the mismatch concept of the developmental origins of the developmental origins of health and disease,* Pediatr Res *61:5R, 2007.)*

and neurotransmitter biochemistry and function have far-reaching consequences on subsequent neurobehavior.[107] Pathophysiologically, all the presenting features related to the developmental origins of adult disease are due to changes in cellular structure and function, both secondary to altered nutritional or hormonal/metabolic milieu during critical developmental phases of life. Sex-dependent changes in phenotype are observed related to the influence of sex steroids on many of these pathophysiologic mechanisms (Fig. 13-3).[29]

Based on the organs most involved, epidemiologic studies have borne associations, and animal investigations have deciphered mechanisms in specific organs that underlie the ultimate adult phenotype based on developmental origins. In addition to the original observations of cardiovascular disease, insulin resistance/diabetes mellitus, hypertension, and dyslipidemia, other phenotypic features reported consist of stroke, kidney and liver failure, structural abnormalities with concomitant changes in function of the lung resulting in airway disease, immune dysfunction, osteoporosis, and psychiatric disorders related to changes in the brain secondary to stressors (Box 13-1). More recently, investigations have also included an association related to cancers, supporting a developmental origin for this dysregulation in cell proliferation and growth along with a shortened life span (see Box 13-1).[56,99]

CANCER

Most cancers are diagnosed later in life. The pathogenesis of cancer is multifactorial. Breast cancer incidence varies throughout the world. The incidence is increased in American and European women compared with Asian women. After a couple of generations, the incidence of daughters of Asian immigrants approaches the incidence of women in their adopted Western country.[100] Although numerous oncogenes have been identified, genetics and environmental triggers cannot completely explain the pathogenesis of cancer. An array of epidemiologic data has accumulated that supports the hypothesis that cancer has in utero origins.[23,62,65,99] Higher birthweight is positively associated with breast cancer risk later on in life. Estrogen has been implicated as one of the main culprits in breast cancer development. Female sex, age of menarche and menopause, age of first pregnancy, parity,

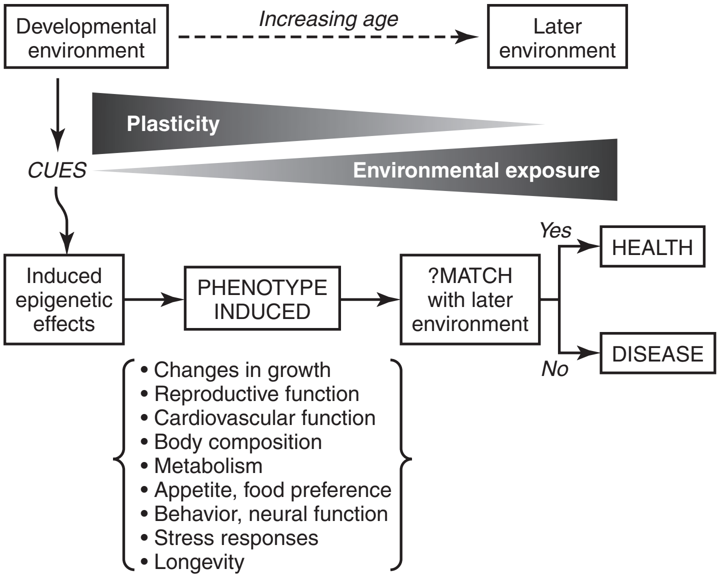

Figure 13–3. Developmental plasticity declines and exposure to environmental challenges increases with age. Epigenetic processes are induced by cues from the developmental environment. They play a role in determining the phenotype of the offspring as part of a life course strategy to match the environment. If not appropriately matched, the risk of later disease is increased. *(From Godfrey KM et al: Epigenetic mechanisms and the mismatch concept of the developmental origins of the developmental origins of health and disease,* Pediatr Res *61:5R, 2007.)*

- Depression, anxiety, bipolar disorder, schizophrenia
- Cancer
- Shortened life span

lactation, and consumption of exogenous estrogens all are associated with an increased disease risk.

Trichopoulos first proposed that elevated estrogen concentrations during pregnancy increase the risk of breast cancer in female offspring.[99] Estrogen concentrations peak during pregnancy, being 10 times higher in pregnant women. Higher maternal estrogen concentrations are noted with advanced maternal age, twin gestations, and LGA status. Conversely, estrogen is inversely associated with pregnancy-induced hypertension. Fetal mammary gland cells are undifferentiated and particularly vulnerable to the carcinogenic effects of estrogens and other growth hormones, such as IGF. As a result, in utero exposure to high estrogen levels increases the risk of mitogenic activity and adult-onset cancer.

In a case-control study performed using the Swedish Cancer Registry, preeclampsia and eclampsia afforded protection against breast cancer. Preeclampsia/eclampsia was associated with a breast cancer odds ratio of 0.24 (P = .013). A clear positive association between breast cancer and higher birthweight, birth length, and placental weight was reported. Further epidemiologic studies have confirmed these findings. For women who weighed 3500 to 3999 g at birth, the adjusted odds ratio for breast cancer is 0.86. In comparison, in women with birthweights less than 2500 g, the adjusted odds ratio is reduced to 0.5.[65] For each 100-g increase in birthweight, the risk for postmenopausal cancer increases approximately 6%.[55] It has also been estimated that there is a 39% increase of premenopausal breast cancer per standard deviation in birthweight for gestational age.[62]

There is also evidence that rapid childhood growth in combination with a higher birthweight can influence risk of breast cancer. In a cohort of more than 2000 female subjects, women who had high birthweights and were tall during childhood had a fourfold increase in breast cancer compared with women who had high birthweights but were either short or average in stature.[1] The subjects' stature could be a reflection of their in utero environment. Rapid postnatal and childhood growth could also contribute to the development of breast cancer, however. In utero growth influenced by pregnancy estrogens with or without rapid childhood growth is linked to the development of breast cancer in female offspring. In addition, similar associations have been noted with respect to ovarian cancer.[5]

PSYCHOSOCIAL ASPECTS

When examining social consequences of preterm birth, the question of why decreasing gestational age is a risk factor for a less successful adult life is raised. The fetal programming model provides an explanation. Adults who were SGA or were VLBW have remodeling of their hormones and metabolism in early neonatal life from heightened stress responses.[18,61]

This remodeling leads to anxiety and depression as well.[61] Malnutrition during a critical time in prenatal and postnatal development may also play a vital etiologic role. Similarly, fetal origins of adult disease not only help explain why fetal remodeling can affect systemic adult disease processes, but also explain the difference seen in academic performance, professional attainment, sexuality and reproduction, emotionality, personality, and overall quality of life.[2,33,48,69,114]

Improvements in technology and the practice of neonatology have allowed clinicians to adequately resuscitate preterm infants at younger and younger gestational ages. The generations of preterm infants who have survived are now being followed into adulthood, and they provide information on the types of problems facing infants who are SGA, have VLBW, and have extremely low birthweight.[6,7,25,34] The particular medical problems these infants experience are well described in the literature. The social implications of being born premature have not been studied that well, however. Countries in Europe and Scandinavia that maintain national databases are beginning to report their findings on outcomes of preterm birth. Some nationally funded databases in the United States are also starting to examine the social and functional outcomes of preterm birth. Stressors encountered prenatally or postnatally during critical stages of development are associated with mental disorders related to anxiety and depression, including bipolar and schizophrenic disorders.[54,60,80,86] These functional aberrations accompany structural changes that are seen in periventricular leukomalacia that involves an arrest in oligodendrocytic differentiation, and involves a later consequence of Alzheimer disease with loss of neurons and their integrity.[9,22,67,109]

More recently in a Helsinki cohort, fast postnatal growth superimposed on restricted prenatal growth was also shown to influence the development of the trait anxiety in men and women at 63 years of age. This pattern resembled the pattern seen with the development of cardiovascular events, supporting a shared common developmental origin.[54] There is a growing body of evidence supporting an infectious etiology for the subsequent development of schizophrenia and related psychoses. Particularly, fetal or childhood infections with *Toxoplasma gondii* or cytomegalovirus have been associated with psychoses during adult life.[38] Although direct neurotropism is a likely cause, particularly when the infection occurs during a critical window of plasticity, other mechanisms, such as immune factors or inflammation, may be contributors as well.[103] Although a developmental structural basis may contribute to subsequent psychoses, other functional perturbations also play a role. In genetically modified mice, restricted neuronal glucose supply subsequently led to autistic behavior.[113] A developmental origin for a psychological phenotype exists and is being investigated further.

TOXINS, ENDOCRINE DISRUPTERS, AND MICRONUTRIENT METABOLISM

Although considerable focus has been on prenatal and postnatal nutrition as the inciting factor, other factors, such as maternal stress, prenatal glucocorticoids, infections associated with inflammation, and hypoxic-ischemic insults secondary to a diminution of fetal blood flow, seem to affect fetal development resulting in subsequent cardiovascular and metabolic abnormalities.[21] Certain endocrine disrupters, such as estrogens, antiandrogenic compounds, and specific environmental toxin exposures (plasticizers in bottles), have been observed to have far-reaching effects on the phenotype of animals studied.[3,39] (See Chapter 12.) These changes persist into the third generation, particularly in male offspring, when a pregnant animal is exposed. The fetus (second generation) and the gametes of the fetus (which give rise to the third generation) face the same exposure. In the case of the female, the gametes develop postnatally, and any insult during this period can have similar consequences into subsequent generations.[3] Overall, there are sex-specific phenotypes depending on the window of development during exposure and the impact on the developmental profile of a particular tissue. In certain cases, micronutrients that play the role of methyl donors have been protective against adult-onset diseases if introduced at the right time.[58]

TRANSGENERATIONAL PERSISTENCE OF PHENOTYPIC CHANGES

Investigations of survivors of the Dutch famine have revealed transgenerational persistence of phenotypic changes.[73] A similar phenomenon exists with endocrine disrupters when a mother is exposed to diethylstilbestrol, phytoestrogens, or androgens. This exposure sets the next generation and the following for a change in phenotype consisting of an increased incidence of cancers or the development of polycystic ovary syndrome. Animal models showed a similar phenomenon with endocrine disrupters and perturbed nutrition prenatally.[91] Introduction of micronutrients that serve as methyl donors, such as folic acid, methionine, or betaine, was observed to reverse the transgenerational phenotypic changes.[58,105]

These investigations, in particular, generate considerable interest because all pregnant women are given multivitamins and receive folic acid prenatally. A woman who has given birth to an infant with a neural tube defect is given a higher dose of folic acid during her next pregnancy to reduce the incidence of neural tube defect. Investigations introducing docosahexaenoic acid (omega-3 fatty acids) in the maternal diet have also had a positive impact on the life course of the offspring exposed to nutritional deprivation in utero.[70] A debate is ongoing whether folic acid supplements used in preventing neural tube defects are adequate in the absence of obvious side effects.[46] Further studies from developing countries reveal that micronutrients such as folic acid or zinc are important, and deficiencies can also perturb adult health and potentiate chronic disease.[84,112] These observations collectively led to interrogating the role of genetics in developmental origins of health and disease. In this postgenomic era, this role is easy to determine. Rather than actual gene mutations or single nucleotide polymorphisms, the phenomenon of epigenetics involving nonmendelian heritable changes in gene expression, may contribute to the pathophysiology (Fig. 13-4).

Maternal undernutrition and overnutrition seem to cause similar effects on the offspring, resulting in a perpetuation of

chronic diseases that seem to expand in incidence and severity from generation to generation. The adult who had IUGR survives the adverse intrauterine environment, but becomes maladaptive, developing type 2 diabetes mellitus as an aging adult.[26,43] This phenotype is evident particularly in males, whereas females adapt toward a more insulin-sensitive phenotype.[28] When a woman who had IUGR becomes pregnant, glucose intolerance emerges, however, manifesting as gestational diabetes.[12] Gestational diabetes, caused by either insufficient insulin production to meet the demands or emerging insulin resistance, affects the developing offspring. The progeny of a mother who had IUGR bears the propensity of developing features akin to an infant of a diabetic mother.[12,96] Independent investigations at the other end of the spectrum—maternal diabetes or obesity—show metabolic derangements in the offspring consistent with insulin resistance, childhood obesity, and type 2 diabetes mellitus.

While the mechanisms behind such a phenomenon[12,13,95,102] are being unraveled, animal models diverge from the human situation because the latter *tends* toward an intrauterine environment of plenty manifesting as neonatal obesity (macrosomia) or appropriately sized offspring but with a redistribution of fat stores.[13,102] In animal models, the fetus emerges as a growth-restricted offspring related to the extreme nature of perturbations created in the mother (e.g., consistent and severe hyperglycemia) or by involving other mechanisms. Maternal hypercholesterolemia is known to cause hypoaminoacidemia and IUGR.[11] Offspring exposed to maternal hypercholesterolemia in utero express normal cholesterol values, but develop an increased incidence of atherosclerosis in adulthood.[11]

Phenotypically, the most dramatic report has been the observation that gestational diabetes in a rat offspring with IUGR resulted in a diabetic mother in the next generation.[12,45] These investigations suggested that the fetal origins of adult disease did not rest with one generation, but were transgenerational. Similar observations were made in calorie-restricted and protein-restricted rat mothers when the impact was seen not only in the offspring, but also in the next generation, related to defective insulin secretion and insulin sensitivity.[77] Additional investigations of gestational undernutrition in the grandmother revealed persistence of insulin secretory defects, with the paternal inheritance playing a more prominent role in growth and size, and the maternal inheritance influencing metabolism in the grandchild's generation in mice.[45] When studies normalized the intrauterine environment of an adult rat offspring that had IUGR by embryo-transfer experiments, these changes in insulin secretion and sensitivity persisted into the next generation, supporting the concept of epigenetics.[94]

EPIGENETICS

Waddington coined the term *epigenetics* and defined it as a branch of biology that studies the causal interactions between genes and the phenotype.[101] Epigenetics consists of covalent changes of the genome that do not alter the DNA sequence, but are inherited through mitosis and meiosis. Epigenetics is essential for gene expression and the cell cycle, and forms the important link between environment and genome. The genome manipulates the ultimate phenotypic presentation. The genome of immature primordial germ cells of the developing embryo (zygote and blastomeres) undergoes extensive demethylation supporting totipotency. This erasure of methylation marks represses the somatic program. Subsequently during gametogenesis, these methylation marks are preserved in a sex-dependent manner, providing for pluripotency, and are maintained through several rounds of mitosis and cell differentiation.

Subtle changes in DNA methylation occur through the rest of fetal development and subsequently during extrauterine life, explaining the phenotypic differences with age in monozygotic twins. Although DNA methylation relies on the one-carbon metabolism involving methyl donors (folic acid, methionine, betaine), DNA is methylated in specific noncoding regions and at DNA repeats of transposable elements. In particular, CpG islands of a gene promoter are unmethylated in tissues of expression, but can undergo methylation in tissues where that particular gene is not expressed. Although dietary intervention may alter the percentage of methylation, it generally does not completely erase methylation marks as is known to occur during gametogenesis.[20,74]

DNA methylation plays a significant role in regulation of the cell cycle during proliferation and cancerous changes.[56] In addition to DNA methylation, post-translational covalent changes in the histone code have been observed to play a role in gene expression. Histone proteins form the backbone around which DNA wraps, and depending on the covalent modifications of amino acid residues on the N-tail, the structure of chromatin can vary from heterochromatin (tightly wound) to euchromatin (loosely wound). This variation allows for repression (heterochromatin) or activation (euchromatin) of the downstream genes. Histone residues can be modified by acetylation, phosphorylation, methylation, and ubiquitination. Other processes consisting of proline isomerization, sumoylation, deimination, and ADP-ribosylation can also occur. Depending on the residue and its location, acetylation and phosphorylation activate generally, whereas methylation deactivates gene expression.[20] Studies surrounding the pancreatic β-islet cells, skeletal muscle insulin responsive glucose transporter 4, leptin-induced hepatic gene expression, IGF-II, glucocorticoid receptor, peroxisomal proliferator activated receptor-α, and phosphoenolpyruvate kinase enzyme promoters have been performed in animal models of IUGR.[31,58,75,81,98]

Histone modifications in key residues lend themselves to a sex-specific difference in gene expression, which alters the ultimate phenotype. In contrast to histone modifications that are easily detected, changes in DNA methylation secondary to nutritional perturbations are rarely found, as in the IGF promoter in humans exposed as first-trimester fetuses to the Dutch famine or in genes that bear transposable elements.[37] The concept of epigenetics regulating developmental origins of health and disease has evolved, however, and experiments undertaking embryo transfer in animals have provided further support to this concept of epigenetics playing a role in retaining genetic information in the chromatin of a cell through generations.[94] Epigenetics links the in utero developmental environment to altered gene expression. Further investigations have revealed that even postnatal maternal nurturing tendencies can alter the glucocorticoid receptor in the brain by epigenetics involving aberrant DNA methylation and histone modification.[106] These changes dictate whether the next generation displays strong mothering qualities or not. The environment-gene interaction is determined by chemical changes, which affect the process of gene transcription or repression.

The discovery more recently of noncoding small RNAs has opened a new field of microRNAs, which also play an important role in epigenetics by modifying gene expression post-transcriptionally.[14] MicroRNAs indirectly affect translation of key factors or enzymes required for epigenetic processes in the nucleus. MicroRNAs bind to specific complementary sequences in the 3′-untranslated region of a gene suppressing translation. By suppressing DNA methyltransferase enzyme translation, microRNAs indirectly can regulate DNA methylation. There is significant accumulation of structural evidence in vivo using animal models that supports a role for epigenetic mechanisms in developmental programming. Similar changes establishing a cause-and-effect paradigm are lacking, however. Further convincing evidence in support of such phenomena in human samples from infants who are LGA, are SGA, have IUGR, and have VLBW, who subsequently develop chronic disorders, still needs to be accumulated (Fig. 13-5).

Overall, an aberrant environment during a critical phase of development imposes permanent adaptive changes as a mode of survival. These adaptations are mediated by epigenetic alterations of the genome, which changes gene expression. Changes in gene expression affect the cell cycle and phenotype and are carried transgenerationally. This phenomenon underlies the concept of developmental origins of adult health and disease.

TRANSLATION TO NEONATOLOGY

How do these epidemiologic associations in humans and mechanistic paradigms discovered in animal models affect neonatology? Meta-analysis of 18 epidemiologic studies supports a relative risk of adult coronary disease of 0.84 for each 1-kg increase in birthweight.[32] A reduction or increase of birthweight approaching 1 kg is usually not seen within term infants in response to maternal changes (e.g., maternal smoking reduced birthweight by 300 g or nutritional supplementation in chronic undernourished women increased mean birthweight by only 136 g).[68] The epidemiologic associations of either a reduction or an increase in birthweight with adult-onset chronic diseases have significantly accumulated, however[47] (e.g., the association of adult-onset insulin resistance is seen with a 200-g reduction in birthweight[7]).

In practice, changes of 1 kg in birthweight are possible and seen in infants with IUGR (approximately 2 kg), premature infants (approximately 1.5 kg), and infants who are LGA (approximately 4 kg) compared with their term counterparts who are appropriate for gestational age (3 kg). It has become apparent that intrauterine and postnatal macronutrition and micronutrition and growth trajectories have far-reaching implications to an individual. Further postnatal interventions (nutritional or otherwise) can cause lifelong perturbations requiring close long-term follow-up. Particularly, postnatal nutrition results in walking a fine line between guarding against “nutritional excess” while ensuring adequate energy for the developing brain.

The recognition of variability in a given population based on ethnicity, prenatal nutrition, stressors, preeclampsia and placental health, infections, and toxin exposure is important. An example is growth rate and nutritional practices that vary based on ethnicity and the country/region of origin. An ideal growth pattern for the West may not be reflected or achieved in certain South Asian countries. Although infants may be smaller in size, their body composition may be entirely different. More evidence is emerging that body mass index measurements may not reflect the whole picture. Fat distribution plays a major role in whether an infant is prone to developing obesity and insulin resistance with time. Individuals who have subcutaneous fat accumulation may be relatively more protected than individuals with visceral adiposity. Further signs of lipotoxicity seen with fat redistribution and accumulation in tissues such as the liver, β-islet cells of the pancreas, skeletal muscle, and bone marrow are detrimental to metabolic homeostasis. Various biomarkers, such as circulating

Figure 13–5. Simplistic scheme showing methylation (CH_3) of CpG islands achieved by DNA methyltransferases (Dnmts) and *S*-adenosyl-L-methionine. Methylated DNA attracts methylated CpG binding protein 2 (MeCP2), which recruits histone deacetylases and histone methylases resulting in histone deacetylation and methylation. When this occurs in a gene promoter, it causes heterochromatin formation, repressing gene expression. This is facilitated further by heterochromatin protein (HP1) binding. In contrast, hypomethylation of DNA attracts histone acetylases and demethylases, which have the opposite effect resulting in euchromatin formation, transcription factor (TF) binding, and activation of gene transcription. insulin (C-peptide), leptin, and adiponectin concentrations, are considered to preempt childhood and adolescent disorders secondary to insulin resistance.

Similar approaches are emerging with respect to the development of other chronic disorders, such as hypertension and neuropsychoses. Although the search for an ideal battery of biomarkers that can predict the adult phenotype of an infant is ongoing, the prenatal and postnatal periods of life form the critical window of developmental plasticity that contributes to the entire life cycle of the individual, including the phenotype of future generations.

SECTION III

Pregnancy Disorders and Their Impact on the Fetus

CHAPTER 14

Intrauterine Growth Restriction

Robert M. Kliegman

Fetal development is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation that are influenced by the maternal environment, uteroplacental function, and the inherent genetic growth potential of the fetus.[5,6,31,34,47,73] When circumstances are optimal, none of these factors has a rate-limiting effect on fetal growth and development. Neonates subjected to aberrant maternal, placental, or fetal circumstances that restrain intrauterine growth are a high-risk group and are traditionally categorized as having intrauterine growth restriction (IUGR). The cumulative effects of adverse environmental conditions and aberrant fetal growth threaten continued intrauterine survival; labor, delivery, and neonatal adaptation become increasingly hazardous. Similarly, postneonatal growth and development may be impaired as a result of IUGR and the subsequent problems encountered during the neonatal period. Neonates who have IUGR are a heterogeneous group. Many with IUGR may have poor intrauterine growth as an adaptation to a suboptimal uterine environment.

The terms *intrauterine growth restriction* and *small for gestational age* (SGA), although related, are not synonymous.[16,49,76] IUGR is a deviation from, or a reduction in, an expected fetal growth pattern, and is caused by innate reduced growth potential or by multiple adverse effects on the fetus. IUGR is the result of any process that inhibits the normal growth potential of the fetus. Fetal growth at term may be predicted by anthropometric analysis of fetal dimensions with second-trimester ultrasonography. In addition, fetal growth curves may be constructed for an individual fetus based on maternal height and weight, parity, ethnicity, and fetal gender (www.gestation.net).[4] Deviations from the predicted weight at term may result in an infant with IUGR, but may not result in an infant who is SGA. SGA describes an infant whose weight is lower than population norms or lower than a predetermined cutoff weight (e.g., −2 SD, 5%, 10%); the cause may be pathologic, as in an infant with IUGR, or nonpathologic, as in an infant who is small but healthy. Not all infants who are IUGR are SGA: compared with siblings, ethnically derived fetal growth curves, or their own growth potential, infants' birthweight may be less than expected despite their weight being above an arbitrary normative population growth percentile standard. A customized birthweight would take into consideration important epidemiologic variables such as parity, maternal anthropometrics, and ethnicity. (See growth curves in Appendix B.) Infants with IUGR but who are not SGA remain at increased risk for fetal distress and neonatal hypoglycemia.

Low birthweight as a classification includes premature infants (younger than 37 weeks), preterm infants who are SGA (younger than 37 weeks), and term (37 weeks or older) infants who are SGA. Many preterm infants are also IUGR when growth is based on fetal growth standards. These IUGR preterm infants are at increased risk for perinatal death and neonatal complications.[4,16]

FETAL GROWTH AND BODY COMPOSITION

Through anthropomorphic measurements that include fetal weight, length (crown to heel), abdominal circumference, and head circumference and three-dimensional fetal ultrasonography, fetal growth standards have been determined for various reference populations from various locations.[4,76] Although the range of birthweight at each gestational age in these populations may vary (Table 14-1), the overall pattern of fetal growth (Fig. 14-1) is representative of these and subsequent groups. Early and late fetal growth patterns appear to be linear, beginning at approximately 20 weeks' gestation and lasting until 38 weeks; thereafter, the *rate* of weight gain begins to decline. Fetal growth curves based on prematurely born infants may result in inaccurate assessment of fetal growth. Premature infants often have IUGR and skew the fetal growth curve to standards lower than those that would have been obtained if the fetus had not been born early. (See growth curves in Appendix B.)

TABLE 14–1 Birthweights from Six Sources

Nearest Week of Gestation	MEAN BIRTHWEIGHT (g ± 1 SD) Denver	Baltimore	Montreal	Portland	Chapel Hill	12 U.S. Cities (Cluster Method)

From Naeye RL, Dixon JB: Distortions in fetal growth standards, *Pediatr Res* 12:987, 1978.

Near term, the fetal weight gain appears to decelerate; after birth, it again assumes the intrauterine rate (Fig. 14-2). Fetal weight gain (grams per day) is constant during the second trimester and accelerates during most of the third trimester, but it declines near term. During the neonatal period, the rate of gain accelerates again. This relative slowing of growth as a normal fetus approaches term may be caused by some mild restraint of fetal growth. These restraining factors may be related to uterine size or placental function. Some fetuses continue to grow in utero, however, after week 40. During the neonatal period, growth resumes and approaches the in utero rate when this restraint has been eliminated.

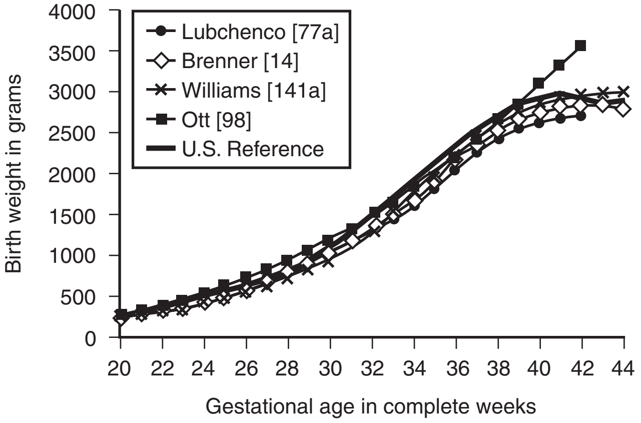

Figure 14–1. Fetal weight as a function of gestational age by selected references. *(From Alexander GR et al: A United States national reference for fetal growth,* Obstet Gynecol *87:163, 996.)*

Although weight gain per day is maximal before term, when growth is expressed as percent increase per day, it is greatest during embryonic and early fetal development (see Fig. 14-2). In the last half of pregnancy, a fetus gains 85% of birthweight. The nature of fetal growth differs, however, between early and later fetal life. During the embryonic and early fetal growth period, tissues and organs increase in cell number, rather than cell size (hyperplastic phase of cell growth, when total DNA content increases in new tissues). Later phases of growth include a period when cell size also increases (protein and RNA content), along with continued enhancement of cell number (mixed hyperplastic and hypertrophic phase). In brain (especially the cerebellum) and muscle, this phase of growth may continue through the second year of life (brain) and adolescence (muscle). The final stage of growth is a purely hypertrophic phase, when only cell size increases.

The contribution of each tissue to body weight changes during fetal and postnatal development is depicted in Table 14-2. Muscle represents only 25% of fetal and neonatal body weight; when full adult maturity has been achieved, it accounts for 40% of the body's mass. Fetal muscle growth and all protein synthesis in the fetus depend on active transport of essential amino acids across the placenta. When provided with these precursors, fetal protein synthesis is autonomous and results in the net synthesis of proteins that have amino acid patterns

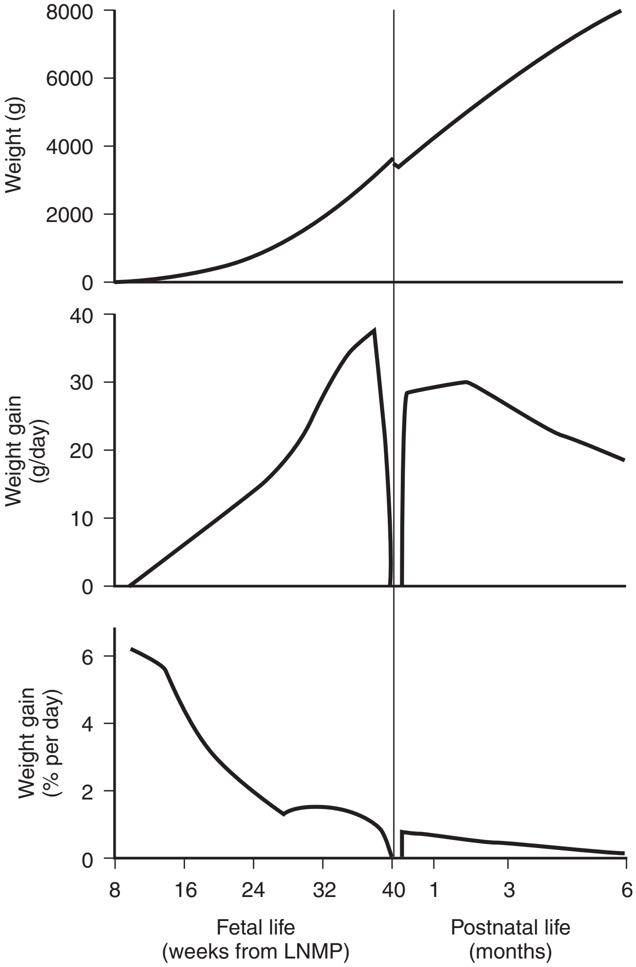

Figure 14–2. Smoothed curves for fetal and postnatal growth in total grams, in grams gained per day, and expressed as percent increase of body weight per day. LNMP, last normal menstrual period. *(From Usher R et al: In Davis J et al, editors:* Scientific foundations of pediatrics, *Philadelphia, 1974, Saunders.)*

TABLE 14–2 Contribution of Organs to Body Mass during Development

Tissue	Fetus (20-24 wk) (%)	Term Infant (%)	Adult (%)
Skeletal muscle	25	25	43
Skin	13	15	7
Skeleton	22	18	18
Heart	0.6	0.5	0.4
Liver	4	5	2
Kidneys	0.7	1	0.5
Brain	13	13	2

From Widdowson E: In Assali N, editor: *Biology of gestation* (vol 2), New York, 1968, Academic Press.

determined by the fetal genome. Although the building blocks may be the same, developmentally the fetal muscle has a lower fibrillar protein content, whereas the sarcoplasmic protein concentration remains unchanged as maturation proceeds. Besides immunoglobulins that cross the placenta, all protein present in the fetus has been synthesized de novo by fetal tissue.

Paralleling the patterns of fetal growth, the macromolecular composition of the body also undergoes sequential patterns of change. One general trend includes a decrease of total body and extracellular water content as the fetus and infant mature (Fig. 14-3 and Table 14-3). Simultaneously, there is an increase of body protein and fat content (Fig. 14-4). Although the increase of tissue protein is gradual during development, the increase of fetal body fat is delayed until the third trimester. When initiated, the deposition of subcutaneous and deep body adipose tissue accelerates more rapidly than the rate of protein accumulation.[33] Infants with IUGR have a smaller percent body fat (17% versus 23%), which is mainly a reduction of subcutaneous adipose tissue, rather than intra-abdominal adipose tissue.[9,50,65]

Coinciding with the changes in the extracellular fluid space, the sodium and chloride concentrations in the fetus decline, whereas the expansion of the intracellular fluid space results in an increase in potassium concentration (see also Chapter 35, Part 1). The decline in total body sodium is less than that for chloride because sodium is also a component of fetal bone. Calcium, phosphorus, and magnesium are nevertheless the major minerals in bone. By term, the total body calcium-to-phosphorus ratio is 1.7:1.8, with 98% of calcium, 80% of phosphorus, and 60% of magnesium deposited within the bone.

FETAL METABOLISM

Maternal and fetal nutritional deprivations can adversely affect fetal growth. The fetus depends on maternal nutrient intake and on maternal endogenous substrate stores as precursors for fetal tissue synthesis and as fuel for fetal oxidative metabolism. The oxygen consumed by the fetus provides energy to support essential fetal work, such as maintenance of transmembrane potentials and replacement of tissue components that are continuously being renewed. In addition, fetal oxygen consumption is required for net synthesis of complex macromolecules such as DNA, RNA, protein, and lipid. Each 1 g of protein synthesized requires the expenditure of 7.5 cal, whereas 1 g of triglycerides requires 11.6 cal. Because 4.85 cal uses 1 L of oxygen, net tissue synthesis represents a substantial proportion of fetal oxygen consumption, which is approximately 4 to 6 mL/kg per minute. The energy cost of neonatal growth as measured in premature infants constitutes the energy stored in tissue plus that expended for the synthesis of that tissue. Total energy cost per 1 g of new tissue is approximately 5.7 cal, whereas that remaining in structural or depot macromolecules represents 4 cal. To produce 1 g of new tissue, 1.7 cal is expended. A similar relationship should occur in the fetus during the third trimester because energy requirements for growth should not change after birth.

Maternal metabolic adjustments during pregnancy are characterized by fuel and hormonal alterations that attempt to secure a continuous provision of substrates for use by the fetus. During normal periods of alimentation, sufficient substrates are presented to the uteroplacental circulation while maternal fuel stores are simultaneously enriched. During the third trimester, maternal insulin resistance and decreased insulin production may partition ingested fuels toward the fetus. When fasting occurs during pregnancy, fuel mobilization is accelerated, as is evident by the rapid increase of maternal free fatty acids and ketone bodies. This accelerated mobilization of maternal adipose tissue stores is facilitated by a rapid decline of maternal insulin levels and an enhanced secretion of the placental hormone, human placental somatomammotropin.

Somatomammotropin has lipolytic activity and may also directly diminish maternal glucose oxidation. In addition, maternal glucose use is attenuated because free fatty acids and ketones replace glucose as a fuel in maternal tissues, whereas hypoinsulinemia reduces glucose uptake in the insulin-dependent tissues of the mother. Fetal glucose provision may be continued. In addition, alternate substrates mobilized during maternal fasting, such as ketones, cross the placenta and may maintain fetal oxidative metabolism. Ketones may be oxidized or serve as precursors for fetal lipid or protein synthesis. This accelerated mobilization of maternal fuels can ensure fetal growth during short periods of maternal fasting; however, prolonged periods of starvation adversely affect fetal outcome.

The substrates used to maintain fetal oxygen consumption have been most accurately determined in ovine fetuses (Table 14-4). Glucose accounts for approximately 50% of fetal energy production in sheep when the mother is maintained in a high nutritional plane. Amino acids, in addition to functioning as precursors for fetal protein synthesis, serve as an oxidizable fuel; they may contribute up to 25% of ovine fetal oxygen uptake. Taken together, lactate and acetate may supply an additional 25%. Data from human pregnancies suggest that glucose oxidation may contribute a greater proportion of fetal energy production than in the ovine fetus.

Similarly, the fetal respiratory quotient has been estimated to be close to 1 in other mammalian species, which suggests that carbohydrate oxidation is the predominant source for fetal oxidative metabolism. Fasting during human pregnancy may result in an alteration of substrates presented to the fetus when maternal and subsequently fetal ketone bodies increase. Although free fatty acids, especially the essential fatty acids, must cross the placenta, their role in fetal energy production and adipose tissue growth is limited because the essential fatty acids are probably deposited in structural tissues (Fig. 14-5).

In addition to the provision of substrates for fetal oxygen consumption and growth, tissue growth depends on an

appropriate fetal endocrine milieu. Among the hormones, insulin and insulin-like growth factors (IGFs) have been implicated as "growth hormones" of the fetus.[23,27,38,48,51,74] Because insulin does not usually cross the placenta, this growth-enhancing hormone must be of fetal origin. Insulin promotes fetal deposition of adipose and glycogen stores, while potentially stimulating amino acid uptake and protein synthesis in muscle. In the absence of fetal insulin production, as in conditions such as pancreatic aplasia, transient or permanent neonatal diabetes mellitus, or congenital absence of the islets of Langerhans, fetal growth is severely impaired.

Knockout mice models of imprinting defects produce fetuses with IUGR when the *paternal IGF2* or insulin genes are removed, but fetuses that are large for gestational age when the *maternal H19* or *IGF2r* genes are knocked out. When the peripheral action of insulin is attenuated by diminished receptor or postreceptor events, as in leprechaunism and Rabson-Mendenhall syndrome, fetal growth may be impaired (Table 14-5).[12,23,38,44,52] Insulin resistance resulting from insulin receptor gene mutations without the phenotype of leprechaunism, and potentially caused by mutations in the postreceptor phosphorylation products such as insulin receptor substrate-1 of the insulin receptor signal transduction pathway, may produce IUGR and postnatal growth restriction. As adults, these patients may manifest diabetes mellitus.

Fetal monogenic disorders that affect fetal insulin secretion or action may produce IUGR. Alterations of the fetal glucokinase gene, which facilitates insulin release after it senses elevated ambient glucose concentrations in the pancreas, result in IUGR when the mutation produces reduced enzyme function. Fetal weight reduction owing to a loss of function mutation may be 500 g. As an adult, the affected patient would manifest diabetes mellitus. If the mother also has this mutation, she probably has diabetes type II and is hyperglycemic, which may attenuate the fetal growth restriction in an affected fetus. In contrast, gain of function mutations of this pancreatic glucose-sensing enzyme enhance fetal insulin secretion and may increase fetal weight. Another genetic cause of fetal hyperinsulinism is the mutation of the sulfonylurea receptor of the potassium inward rectifier channel. Persistent activation of this channel causes fetal hyperinsulinism and enhanced fetal weight.

Pancreatic agenesis (homozygous mutation of insulin promoter factor-1) and transient neonatal diabetes (paternal isodisomy or duplication of chromosome 6q22-q33) are also associated with IUGR. Leprechaunism (homozygous or compound heterozygous severe insulin receptor mutation) produces IUGR secondary to insulin resistance.

Neonates having prolonged periods of hyperinsulinism in utero, such as infants of diabetic mothers or infants with Beckwith-Wiedemann syndrome (imprinting defect with hypermethylation of *H19* gene) or persistent hyperinsulinemic hypoglycemia (nesidioblastosis), have enhanced adipose and muscle tissue mass, resulting in excessive birthweight (see also Chapter 49, Part 1). Beckwith-Wiedemann syndrome may be due to epigenetic mutations that are opposite to the mutations seen in Silver-Russell syndrome (see Table 14-5). Beckwith-Wiedemann syndrome has been reported after assisted reproductive technology, potentially from alterations of DNA methylation secondary to availability of methyl donating precursor compounds in the incubation media.[7,37,59] Beckwith-Wiedemann syndrome has also been reported in one sibling of a monozygotic twin sibship, suggesting that epigenetic/imprinting errors enhance or interfere with fetal growth. Transient neonatal diabetes is also due to loss of imprinting (methylation) at chromosome 6q24 or paternal uniparental isodisomy 6; it is associated with IUGR, and the degree of IUGR is related to the severity of the imprinting defect. Infants with transient neonatal diabetes mellitus recover and become insulin independent at 3 to 4 months of age, but develop type II diabetes mellitus in young adulthood. Imprinting defects may also affect placental function and nutrient supply to the fetus.[8,10,18,26,32,44,55,58,67]

Fetal growth hormone probably does not influence fetal growth because there are few growth hormone receptors on fetal liver. The birthweight of a fetus with panhypopituitarism is similar to that of a normal fetus. Nonetheless, fetal length may be reduced in the presence of growth hormone insensitivity as a result of a growth hormone receptor deficiency. Maternal levels of placenta-derived growth hormone are low in cases of IUGR. Placental growth hormone increases maternal nutrient provision to the fetus and is thought to enhance mobilization of maternal substrates for fetal growth.

The final common pathway of growth hormone action is mediated by the generation of IGFs. IGF1 is a single polypeptide encoded on chromosome 12. IGF1 messenger RNA (mRNA) and its receptor are present in many fetal cells and are not regulated by growth hormone.[12] IGF2 is a single polypeptide and is encoded on chromosome 11. Its mRNA is 200-fold to 600-fold more abundant in most fetal tissues than mRNA for IGF1. IGF1 and IGF2 are 60% homologous to each other and 40% homologous to insulin. IGF1 may be regulated by substrate availability. The level of IGF1 declines in fetal models of IUGR but increases in infants who are large for gestational age. Fetal levels of IGF1 correlate best with fetal weight. IGF1 and IGF2 receptor binding initiates transmembrane signaling, which activates cell metabolism and DNA synthesis.

IGF1 and IGF2 are present in fetal plasma by 15 weeks of gestation. Nonetheless, plasma levels may not reflect

TABLE 14–5 Mutations Causing Intrauterine Growth Restriction in Humans

Gene(s)	Disorder	Major Clinical Features	Comments
IGF1	IUGR–short stature	Severe prenatal and postnatal growth failure, microcephaly, deafness, carbohydrate intolerance	Based on reports of three families
IGF2, H19	Silver-Russell syndrome	Severe prenatal and postnatal growth failure	Epigenetic mutation chromosome 7 or 11
IGF1R	IUGR–short stature	Severe prenatal and postnatal growth failure, variable CNS abnormalities	Variable increases in circulating levels of IGF-1
Insulin	Congenital diabetes	Fetal growth restriction, diabetes mellitus	10% of cases of permanent neonatal diabetes mellitus
KCNJ11, ABCC8 (KATP channel)	Congenital diabetes	Fetal growth restriction, diabetes mellitus, transient or permanent	40% of cases permanent neonatal diabetes mellitus, CNS disease in some *KCNJ11* mutations; activating mutations
Chromosome 6 ICR abnormality	Congenital diabetes	Fetal growth restriction, transient diabetes mellitus	70% of transient neonatal diabetes mellitus; associated with paternal isodisomy; chromosome 6 or DNA methylation variation
IR	Donohue syndrome (leprechaunism), Rabson-Mendenhall syndrome	Fetal growth restriction, diabetes mellitus, moderate to severe insulin resistance	Treatment with recombinant human IGF-1 may be beneficial
PTF1A, IPF1	Pancreatic agenesis	Fetal growth restriction, diabetes mellitus	Cerebellar involvement with *PTF1A*

CNS, central nervous system; IGF-1, insulin-like growth factor type 1; IUGR, intrauterine growth restriction.

Modified from Chernausek SD: Molecular genetic disorders fetal growth. Kiess W et al, editors: Small for gestational age: causes and consequences, *Pediatr Adolesc Med* 13:44, 2009.

tissue-specific action because these proteins act as competence factors for the cell division cycle in a paracrine or an autocrine, rather than an endocrine, manner. Knockout gene models deleting the *IGF1* gene or the paternal *IGF2* gene or both show an additive reduction of fetal growth.

Partial deletion of the *IGF1* gene in humans produces severe prenatal and postnatal growth restriction, sensorineural deafness, and mental retardation. In addition, genetic variations (polymorphisms) of the *IGF1* gene are associated with symmetric IUGR. These children have low circulating IGF1 levels. In adult life, low IGF1 levels are associated with diabetes mellitus and may explain one aspect of the hypothesis regarding fetal origins of adult disease.

IGFs are modulated by six IGF-binding proteins (IGFBPs), which usually attenuate or occasionally enhance IGF bioavailability and are subject to regulatory signals similar to the signals that regulate IGF protein synthesis.[38] Fetal IGFBP-1 serum levels are inversely related to birthweight and may restrict the availability of IGF1 to fetal tissues. In animals, overexpression of IGFBP-1 produces IUGR. Acute fetal hypoxia and possibly fetal catecholamine release reduce IGF1 levels, but increase IGFBP-1 levels in ovine fetuses. Reduced nutrient availability and lower insulin levels associated with some models of IUGR reduce fetal IGF1 levels, whereas they increase IGFBP-1 levels. Fetal IGFBP-3 serum levels usually parallel serum levels of IGF1 and are increased in fetuses who are large for gestational age, but reduced in fetuses with IUGR.

Maternal nutrient availability is also regulated by IGF1. IUGR is associated with reduced maternal IGF1 levels or when IGFBP-1 is increased. In mice, increasing maternal IGF1 levels results in heavier fetal weight; in sheep, maternal IGF1 infusions result in increased fetal glucose levels and enhanced placental amino acid uptake.

Reduced function or production of the IGF1 receptor (IGF1R) is associated with IUGR. This transmembrane heterotetramer is encoded at band 15q26 and is structurally similar to the insulin receptor. Hemizygosity of IGF1R is associated with IUGR in the ring chromosome 15 syndrome.

More complex epigenetic mechanisms, such as imprinting, may regulate fetal growth.[8,10,18,26,32,44,55,58,67] Abnormal expression of a normally inactive gene (loss of imprinting) is seen in Silver-Russell syndrome and transient neonatal diabetes mellitus. Silver-Russell syndrome is characterized by prenatal and postnatal growth restriction; 10% of patients have uniparental disomy of chromosome 7 (maternal). Transient neonatal diabetes manifests with IUGR and may result from overexpression of imprinted paternally expressed genes at 6q24, owing to paternal uniparental isodisomy of chromosome 6, paternally inherited duplication of 6q24, or a methylation (imprinting) defect.

The roles of other hormones, notably corticosteroids and thyroid hormone, have not been well defined for fetal growth.[27] Nonetheless, repeated doses of dexamethasone to the mother reduce birthweight and possibly brain growth. Mutations that affect the metabolism of cortisol may produce IUGR. Placental 11β-hydroxysteroid dehydrogenase inactivates cortisol and reduces cortisol exposure to the fetus. Placental 11β-hydroxysteroid dehydrogenase is reduced in pregnancies complicated by IUGR and in growth-restricted infant girls born to women with asthma.

With thyroid hormone deficiency in individuals with athyrotic cretinism, birthweight is not altered. These hormones probably have a more significant role as regulatory signals for the initiation of maturation and differentiation in fetal tissues (see also Chapter 49, Part 3).

FETAL ORIGIN OF ADULT DISEASES

Reduced birthweight has been associated with certain adult morbidities (see Chapter 13) that would not be obvious based on an understanding of IUGR and its immediate neonatal sequelae.[2,14,54,71] Low birthweight in the fetus has been postulated to lead to the risk of adult-onset hypertension, type II diabetes, obesity, and coronary artery disease. Recognized risks for adult morbidities include infants born thin who exhibit catch-up growth *and* who in later life become obese.

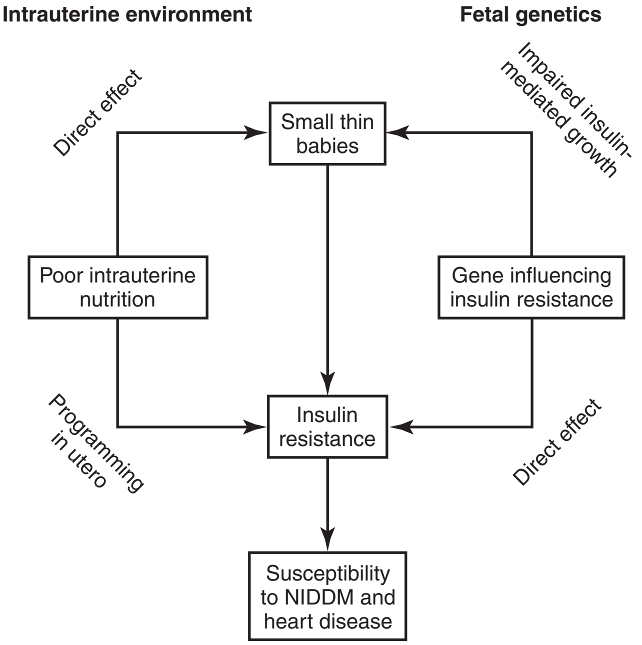
The fetal origin hypothesis states that poor maternal nutrition programs the fetus and produces reduced birthweight and subsequent adult-onset diseases. Many of these studies have not controlled for important covariables, such as the parents' history of hypertension, obesity, or diabetes; race; or socioeconomic status. The risk for these adult morbidities may be only two to three times that of the normal population, so all infants with IUGR are not at risk. Also, twins who are often born with some degree of IUGR do not have a higher incidence of these adult morbidities compared with other adults.

Catch-up growth during infancy and childhood is an established risk factor for the metabolic syndrome. The growth is primarily of central (abdominal) fat and not in lean (muscle) body mass. This growth is often associated with insulin resistance and decreased nutrient-induced thermogenesis. Nonetheless, catch-up growth has been shown to provide a survival advantage to IUGR infants born in developing countries.

Various monogenic disorders also affect birthweight (see earlier). Fetal insulin resistance or poor insulin production may be one primary overriding mechanism, and not the poor maternal nutrition found in some offspring with postnatal insulin resistance. The opposing hypotheses are presented in Figure 14-6.[75]

EPIDEMIOLOGY OF LOW BIRTHWEIGHT

The term *low birthweight* refers to infants born weighing less than 2500 g. The neonatal mortality rate is directly related to the low birthweight rate in a given population. These high-risk infants are a heterogeneous group consisting of infants born preterm (less than 37 weeks) and infants born at term but of reduced weight.[5,6,31,76]



Intrauterine environment
Fetal genetics
Direct effect
Impaired insulin-mediated growth

Susceptibility to NIDDM and heart disease

Figure 14–6. Two alternative explanations for association of small, thin infants with later onset of insulin resistance, non–insulin-dependent diabetes mellitus (NIDDM), and ischemic heart disease: intrauterine environment and fetal genetics. (*From Hattersley AT et al: The fetal insulin hypothesis: an alternative explanation of the association of low birthweight with diabetes and vascular disease,* Lancet *353:1789, 1999. Copyright 1999 by The Lancet Ltd.)*

IUGR is the predominant cause of low birthweight in developing areas and nations with low birthweight rates greater than 10%. Socioeconomic improvement decreases the proportion of IUGR. Of preterm infants, 20% to 40% also have decreased growth for gestational age. Although there seem to be differences in the relative incidence of IUGR and premature birth in different countries, risk factors associated with birth of an infant with low birthweight are similar (Box 14-1).

The rate of reduced weight at term gestation is probably twice as great among African-American infants as among white infants. This difference may be partially independent of socioeconomic factors because infants of African-American parents often have lower birthweight than infants of Hispanic or Asian parents of similar socioeconomic status. The risk of low birthweight is related to the occupation not only of the infant's parents, but also of the grandparents. There is a strong familial aggregation of births of low birthweight in white and African-American families. Provision of adequate nutrition to the future mother and other environmental factors may alter the future mother's growth and future reproductive capability. This intergenerational effect partly explains the observation that mothers of infants of low birthweight were themselves neonates with low birthweight. Although medical complications of pregnancy occur equally in all socioeconomic groups, many adverse behavioral attitudes or practices contribute to the greater low birthweight rates among women of low socioeconomic status.

BOX 14–1 Overview of Risk Factors* for Low Birthweight

DEMOGRAPHIC
- Race (African American)
- Present low socioeconomic status
- Socioeconomic status of infant's grandparents

PREPREGNANCY
- Low weight for height
- Short stature
- Chronic medical illness
- Poor nutrition
- Low birthweight of mother
- Previous infant with low birthweight
- Uterine or cervical anomalies
- Parity (none or more than five)

PREGNANCY
- Multiple gestation
- Birth order
- Anemia
- Elevated hemoglobin concentration (inadequate plasma volume expansion?)
- Fetal disease
- Preeclampsia and hypertension
- Infections
- Placental problems
- Premature rupture of membranes
- Heavy physical work
- Altitude
- Renal disease
- Assisted reproductive technology

BEHAVIORAL
- Low educational status
- Smoking
- No care or inadequate prenatal care
- Poor weight gain during pregnancy
- Alcohol abuse
- Illicit and prescription drugs
- Short interpregnancy interval (<6 months)
- Age (<16 or >35 years old)
- Unmarried
- Stress (physical and psychological)

---

*Many of these variables are risk factors for intrauterine growth restriction (IUGR) and prematurity. These variables are not univariant risk factors, but rather interact in a complex relationship. Only a few factors exert an independent effect. The relationship between African-American race and low birthweight remains a significant factor, with a twofold increase in the incidence of prematurity and IUGR when controlled for other risks.

Modified from Committee to Study the Prevention of Low Birthweight: *Prevention of low birthweight,* Washington, DC, 1985, Institute of Medicine, National Academy Press.

MATERNAL CONTRIBUTIONS TO ABERRANT FETAL GROWTH

Physical Environment

Certain otherwise normal mothers are prone to repeated delivery of infants who are SGA; the recurrence rate may be 25% to 50%.[7,28,40,78] Many of these women themselves were SGA at birth, raising the possibility of intergenerational transmission of a physical regulator of fetal growth. A proportion of these women also remain small throughout life and are identifiable by low prepregnancy weight and stature. These women may exert a restraint on fetal growth by some unknown regulator, possibly related to their own stature, previous nutritional status, endocrine environment, or uterine capacity. In breeding experiments using Shetland ponies and Shire horses, the offspring resulting from breeding a male Shire to a female Shetland was similar in birthweight to a Shetland pony, whereas the birthweight of offspring born to a male Shetland and a female Shire approached that of a Shire. The smaller Shetland female apparently exerts a growth restraint on the genetic potential derived from the larger Shire male. Similar observations are noted in humans. When ova are donated to a recipient mother, the fetal weight correlates best with that of the recipient mother.

Maternal genetic factors have a major direct effect on fetal growth. This influence depends on a transfer of maternal genes, but also on the other, unexplained maternal genetic factors related partly to uteroplacental function. The observation that sisters of mothers with infants who were SGA are at higher risk of carrying fetuses who are SGA than their sisters-in-law gives further evidence of maternal genetic influences on fetal growth. The mother's genetic component to fetal growth is less than 25%.

Paternal factors have less effect on fetal growth. Paternal genes affect fetal growth directly by transfer of genetic material, which may be modified (accelerated or inhibited) by maternal factors. Paternal genotypic potential is best expressed as a function of postnatal growth. Nonetheless, paternal patterns of imprinting of genes by enhancing paternal gene expression or suppressing maternal allele expression may increase fetal growth.

Other constraints on fetal growth may be exerted during multiple gestations because fetal growth declines when the number of fetuses increases. The onset of growth restriction in multiple gestations is also related to the number of fetuses: growth restraint begins sooner with triplets than with twins (Fig. 14-7). In multiple gestations, the uterine constraint seems to occur when combined fetal size approaches 3 kg. Placental implantation site, uterine anomalies, vascular anastomoses, and nutritional factors may also interfere with growth in twin pregnancies.[1,39,57,60,62,63] The uterine capacity itself may also place a constraint on optimal fetal growth. Independent of the number of fetuses, the use of assisted reproductive technologies increases the risk of IUGR.

Maternal Nutrition

Prepregnancy weight and pregnancy weight gain are two important independent variables that affect fetal growth. Underweight mothers and mothers affected with malnutrition deliver infants with diminished birthweight. Weight gain during pregnancy in nonobese patients correlates significantly with fetal birthweight. Poor weight gain by 16 weeks' gestation may predict low birthweight. The effect of prepregnancy weight in obese women is independent of pregnancy weight gain and offsets the frequently observed poor weight gain of overweight pregnant women (Fig. 14-8). Infants who are SGA are unusual for obese women, whereas macrosomia is

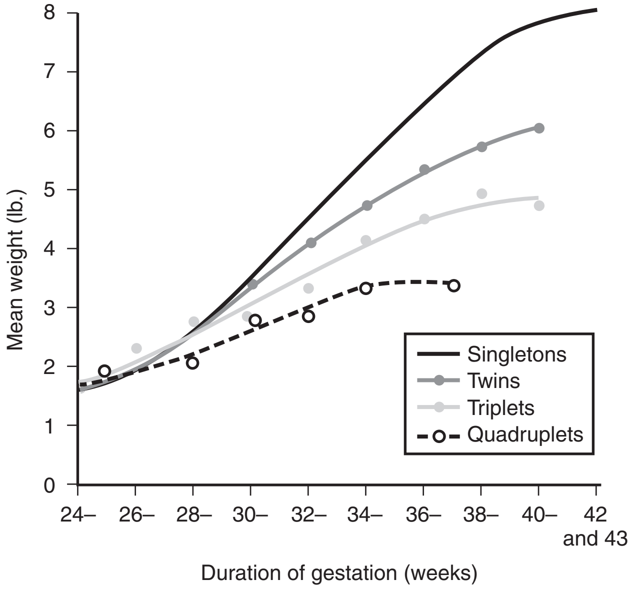

Figure 14–7. Birthweight–gestational age relationships in multiple gestation, denoting origin of aberrant fetal growth. *(From McKeown T, Record RG: Observations on foetal growth in multiple pregnancy in man,* J Endocrinol *8:386, 1952.)*

common. This increased birthweight may be related to large maternal nutrient stores.

Calculating the pregravid body mass index (BMI) helps the clinician determine the target for pregnancy weight gain, which may reduce the risk of IUGR. A low BMI (<19.8) may require a pregnancy weight gain of 12.5 to 18 kg, a normal BMI (19.8 to 26) may require a weight gain of 11.5 to 16 kg, and a high BMI (>26 to 29) may require a weight gain of 7 to 11.5 kg. Obese women (BMI >29) may need a weight gain of only 6 kg. Appropriate weight gain during pregnancy based on BMI may mitigate the risk of IUGR.

The effects of maternal nutritional status on fetal growth are minimal during the first trimester of pregnancy; this is related to the large surfeit of nutrients presented to the small, undemanding embryo and early fetus. As fetal growth accelerates, the requirements for fetal growth increase and may not be sufficiently provided by an inadequate maternal diet. Earlier attempts to limit weight gain in pregnancy with a 1200-kcal diet to prevent preeclampsia resulted in a 10-fold increase in growth restriction. In an otherwise healthy population of Dutch women experiencing a short period of famine during the Hunger Winter of 1944-1945, fetal growth was most severely affected when deprivation occurred in the third trimester. Substrate deficiency during this period resulted in an overall reduction in birthweight of 300 g. Maternal weight gain and placental weight were even more drastically reduced, showing preferential use of nutrients for the fetus. Poor nutrition may also reduce uterine blood flow, placental transport, and villous surface area. Observations similar to those of the Dutch experience occurred during a more severe and prolonged famine in wartime Leningrad, where birthweight was reduced by 500 g at term.

There may be an intergenerational effect of being in utero during maternal starvation. The daughters of women who experienced starvation during the Dutch famine of 1944-1945 have an increased risk of delivering infants of low birthweight if the daughters were exposed to starvation

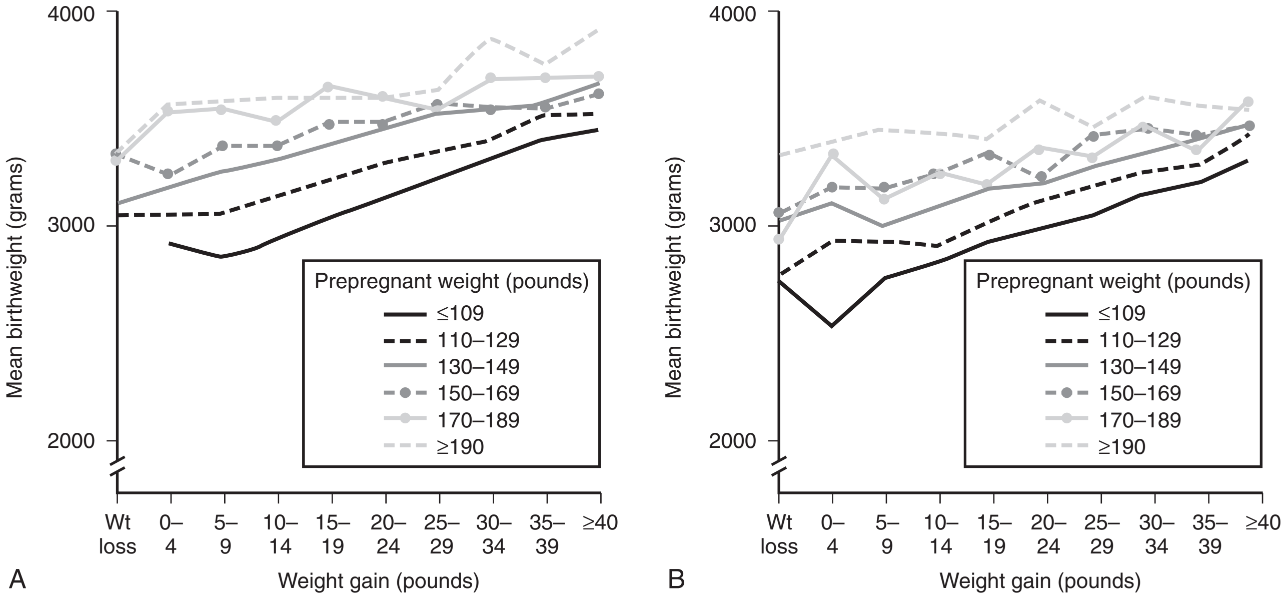

Figure 14–8. A and B, Effect of prepregnancy weight and weight gain during pregnancy among white women (A) and African-American women (B). Note the reduced birthweight at term at all levels of maternal weight variables among African-American women. Also note that weight gain during pregnancy has its most positive effect on birthweight among lean women. Nonetheless, prepregnancy weight among obese, usually nondiabetic, women has the greatest effect on birthweight. *(From Niswander K et al: Weight gain during pregnancy and prepregnancy weight,* Obstet Gynecol *33:482, 1969.)*

in utero during the first or second trimester. The reduction in the next generation's birthweight is approximately 200 to 300 g.

As illustrated in Figure 14-9, decreased caloric intake below critical caloric needs may result in diminished fetal growth. Increased maternal caloric expenditure can occur two ways: excessive physical activity and greater waste of calories. The nutritional aspects of cigarette smoking may be an example of the second way. The diminished heat expenditure that occurs in obese women may result in caloric storage and may partly explain their excessively large infants. Increased maternal storage of calories may be exemplified by the "selfish mother" hypothesis.[75] These women may not develop the usual insulin resistance during pregnancy and may direct ingested calories toward their own tissue stores. These women have fasting hypoglycemia or accelerated disappearance of glucose after intravenous glucose tolerance testing, or both. The opposite occurs among women of low socioeconomic status who receive food supplementation; their skinfold thickness decreases as fetal weight increases.

Decreased transport may reflect placental defects in function, nutrient supply, or blood flow. Decreased blood flow may be caused by peripheral vascular disease or failure to expand blood volume and cardiac output, as in normal pregnancy. Fetuses with insulin resistance or decreased numbers of cells may be unable to grow despite adequate nutrient supply. Examples of fetuses with diminished cell numbers include fetuses affected by rubella embryopathy, autosomal trisomies, and other genetic causes of IUGR.

Attempts at improving the low birthweight outcome in high-risk populations (characterized by having poor nutritional histories) have shown a positive effect of nutritional supplementation. Additional calories, rather than protein supplementation, correlate best with enhanced fetal weight. Caloric supplements greater than 20,000 cal per pregnancy reduced the number of infants with low birthweight; every 10,000 cal supplemented above the standard diet improved fetal weight by an average of 29 g. In Gambia, supplementation during seasonal periods of food shortage resulted in a net positive caloric intake of more than 400 kcal/day. This increased fetal weight 224 g and reduced the low birthweight rate from 28% to less than 5%. A threshold of 1500 kcal/day was observed, which augmented fetal weight when the mother was in positive caloric balance. In the United States, participation in the Women, Infants, and Children (WIC) program has reduced the number of infants who are SGA at birth. Micronutrient supplementation has also been shown to enhance fetal growth in developing countries.[25,29,77]

Protein supplementation may have adverse neurodevelopmental effects on the fetus. Aside from periods of famine and geographic areas where malnutrition is endemic, other conditions associated with poor maternal nutrition and suboptimal fetal growth are included in Box 14-2. Adolescent mothers, in particular, are at risk because of their own growth requirements in addition to those of the fetus.

Certain maternal metabolic aberrations are associated with suboptimal fetal growth. Mothers who have excessively low fasting blood glucose values and mothers whose blood glucose levels are insufficiently elevated after an oral glucose tolerance test are at risk of delivering an infant who is SGA. The "selfish mother" hypothesis has been proposed to explain the poor growth of these infants (see Fig. 14-9).[75]

Chronic Disease

Of all disease mechanisms that interfere with fetal growth, mechanisms resulting in uterine ischemia or hypoxia, or both, have the most extreme effect.[11,21,30,34] Chronic maternal hypertension caused by either primary renal parenchymal disease, such as nephritis, or conditions extrinsic to parenchymal disorders, such as essential hypertension, significantly alters fetal growth and well-being. This effect is related to the duration of hypertension and to the absolute elevation of the diastolic pressure, and is most severe in the presence of end-organ disorders, such as retinopathy. Well-controlled hypertension, without the development of preeclampsia, may not affect fetal growth.

Pregnancy-induced hypertension is of paramount importance to perinatologists in relation to its effect on fetal growth and well-being (see also Chapter 15). This disease, which may affect uteroplacental perfusion and fetal growth long before clinical signs of edema, proteinuria, and hypertension develop, reduces uterine blood flow, as determined by Doppler flow velocity waveforms of the uterine artery. Preeclampsia is characterized by retention of the spiral arteries muscle layer, reduced perfusion of the intervillous space, necrotizing atherosis, and decreased trophoblastic invasion of the decidual spiral arteries. Such trophoblastic invasion depends on decidual laminin, fibronectin, maternal cytokines,

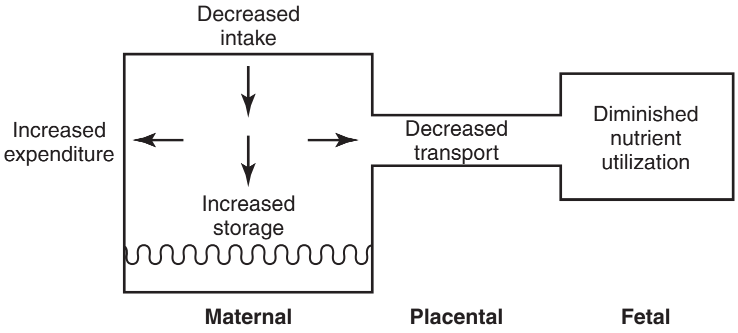

Figure 14–9. Interrelationship of caloric intake and expenditure and fetal nutrient availability. Multiple mechanisms can reduce nutrient availability or use (even in the presence of adequate fuel availability).

BOX 14–2 Women with Poor Nutrition and Risk of Suboptimal Fetal Growth

- Adolescent women, especially unmarried
- Women with low prepregnancy weights
- Women with inadequate weight gain during pregnancy
- Women who have low income or problems in purchasing food
- Women with a history of frequent conception, especially with short interpregnancy intervals
- Women with a history of giving birth to infants with low birthweight
- Women with diseases that influence nutritional status: diabetes, tuberculosis, anemia, drug addiction, alcoholism, or mental depression
- Women known to be dietary faddists or with frank pica
- Women who do heavy physical work during pregnancy

and trophoblastic integrins and proteases. Similar arterial pathologic changes may be present in idiopathic IUGR. In pregnancies complicated by eclampsia, fetal growth deviates from the expected norm from 32 weeks onward (Fig. 14-10). Treatment of hypertension in pregnancy with antihypertensive drugs may contribute further to IUGR; this is independent of the medication. With a decline of 10 mm Hg, fetal weight may be reduced 145 g.

Vascular insufficiency resulting from advanced maternal diabetes mellitus, especially in the presence of end-organ disease in the kidney or retina, also produces IUGR despite the presence of maternal hyperglycemia (see also Chapter 16). Women with serious autoimmune disease associated with the lupus anticoagulant are also at high risk for preeclampsia and IUGR (see also Chapter 18).

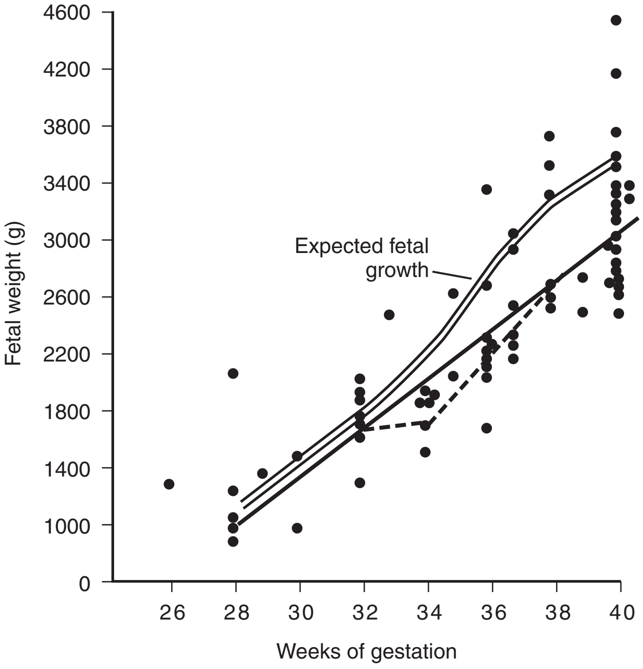

Figure 14–10. Fetal weight after eclampsia. *Broken line* shows mean weight alteration. *(From Zuspan FP: Treatment of severe preeclampsia and eclampsia,* Clin Obstet Gynecol *9:954, 1966.)*

Another major cause of diminished fetal weight gain is maternal hypoxemia. Severe cyanotic congenital heart disease, such as tetralogy of Fallot or Eisenmenger complex, is the best example of this mechanism. Sickle cell anemia is representative of diseases that can produce local uterine hypoxia and ischemia. The maternal morbidity rate is high with cyanotic heart disease. Nutritional anemias usually are not associated with aberrant fetal growth. In sickle cell anemia, the abnormal cells may interfere with local uterine perfusion during episodes of sickling, and growth restriction is observed.

A common and nonpathologic factor related to maternal hypoxia is the diminished environmental oxygen saturation that is present at high altitudes. Infants born in the mountains of Peru have lower birthweights than Peruvian infants born at sea level. Placental mass has hypertrophied in these newborns in an attempt to compensate for the lower circulating maternal oxygen concentration. These neonates are not born with polycythemia as a response to fetal hypoxia, as proposed for other infants who are SGA. The decline in body weight becomes manifest at an altitude of 2000 m, which corresponds to a barometric pressure of 590 mm Hg.

Drugs

The effects of maternal drug administration on the fetus are usually considered primarily in terms of teratogenicity. A continuum of fetal compromise may be present, however, because many malformation syndromes are associated with diminished birthweight, whereas other agents may interfere only with fetal growth. Some drugs associated with IUGR are listed in Box 14-3. (See also Chapters 12, 29, and 38.)

BOX 14–3 Drugs Associated with Intrauterine Growth Restriction

Amphetamines
Antimetabolites (e.g., aminopterin, busulfan, methotrexate)
Bromides
Cigarettes (possibly carbon monoxide, thiocyanate, polycyclic aromatic hydrocarbons, nicotine)
Cocaine
Ethanol (acetaldehyde)
Heroin
Hydantoin
Isotretinoin
Methadone
Methyl mercury
Phencyclidine
Polychlorinated biphenyls
Propranolol
Steroids (prednisone)
Toluene
Trimethadione (Tridione)
Warfarin

Many typically abused drugs have been implicated as agents producing fetal growth restriction by reducing maternal appetite and by being associated with lower socioeconomic groups. At least for heroin, methadone, and ethanol, a cellular toxic effect acting directly on cell replication and growth seems to be involved. This effect is most evident in fetal alcohol syndrome: The prenatal onset of growth restriction persists during postnatal periods despite adequate food intake. A placental transfer block for specific amino acids has been observed in fetal alcohol syndrome.

The effects of cocaine on fetal growth may be multifactorial and may include uterine artery vasospasm, reduced maternal prepregnancy weight, reduced weight gain during pregnancy, and possibly direct fetal endocrine effects. Multidrug use, poor nutrition, and poor prenatal care are common among many women who abuse drugs.

Cigarette smoking during pregnancy reduces eventual fetal birthweight, which is directly related to the number of cigarettes smoked. Birthweight at term is reduced an average of 170 g if more than 10 cigarettes per day are smoked; smoking more than 15 cigarettes per day may reduce birthweight by 300 g. The mechanism of fetal growth restriction is uncertain, but nicotine and subsequent catecholamine release may produce uterine vasoconstriction and fetal hypoxia. Carbon monoxide and cyanide may cause a more direct effect: After binding to hemoglobin, carbon monoxide and cyanide may diminish oxygen unloading from the mother to the fetus and from the fetus to its tissues. Nutritional supplementation does not eliminate the reduced fetal weight completely. The effects of cigarettes may be greatest at advanced maternal age.

Another mechanism producing IUGR is related to the presence of polymorphisms of the genes for glutathione S-transferase and CYP1A1, which are enzymes responsible for the metabolism of polycyclic aromatic hydrocarbons, arylamines, and *N*-nitrosamines. Certain gene polymorphisms may reduce fetal growth by 1285 g at term. Drugs such as propranolol and other beta-blocking agents and corticosteroids probably have a direct effect on the fetus, although the confounding influence of the chronic maternal illnesses for which these agents are prescribed may also contribute to IUGR.

Socioeconomic Status

Poor environmental conditions related to lower socioeconomic status have been associated with infant malnutrition of prenatal and postnatal onset. With improvement of environmental conditions, birthweight is enhanced. This situation was extensively studied after living conditions improved in postwar Japan. The improvement in birthweight during this era occurred only in infants born during the latter part of the third trimester; nutritional and environmental effects seem greatest during this period of fetal growth.

Many maternal factors, such as drug abuse, poor nutritional habits, and cigarette smoking, are interrelated and are covariables associated with poor socioeconomic status. Factors such as adverse environmental living conditions and low levels of education are more prevalent among reproductive-age women of lower socioeconomic status. Adolescent and single-parent families and the failure to seek adequate prenatal advice are also more common. Many investigations have shown that such women are at risk of having infants with IUGR. It has been suggested that if chronic maternal illness and certain behavioral characteristics are eliminated, and prenatal care is available, the remaining women of lower socioeconomic status do not have a higher incidence rate of infants who are SGA. The specific behavioral characteristics more common among poor women are noted in Box 14-1.

PLACENTAL DETERMINANTS

Optimal fetal growth depends on efficient function of the placenta as a nutrient supply line, a metabolic and endocrine unit, and an organ of gaseous exchange. Placental functional integrity requires additional energy production because placental oxidative metabolism may equal that of the fetus. This large energy requirement is essential for maintaining fetal growth-promoting roles, which include active transport of amino acids, synthesis of protein and steroid hormones, and support of placental maturation and growth. Placental growth parallels that of the fetus; however, toward term there is a greater decline in the rate of placental weight gain than in the rate of weight gain by the fetus. During this decline of placental weight, the fetus also exhibits a decrease in the rate of weight change, which suggests that placental function and the rate of weight gain have declined and led to reduced fetal growth.

Despite the change in the rate of placental weight gain, the placenta continues to mature. The placental villous surface area continues to increase with advancing gestational age (Fig. 14-11); simultaneously, the syncytial trophoblast layer continues to thin, and vascularization of the terminal villi continues to improve. Functionally, urea clearance is

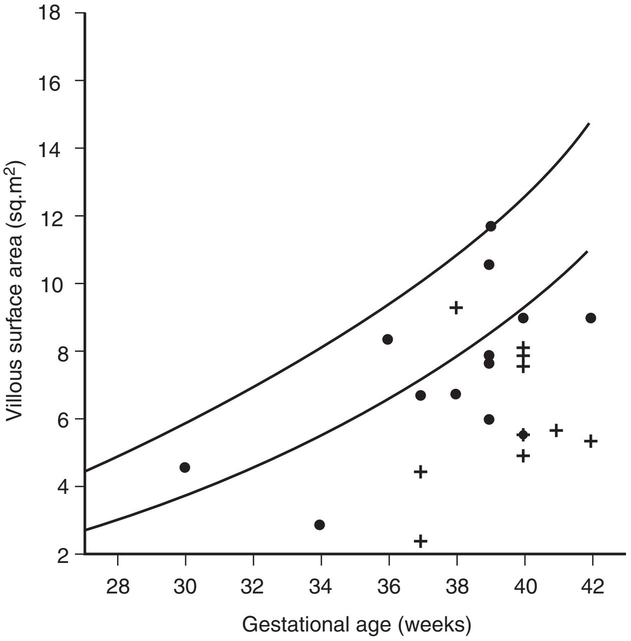

Figure 14–11. Chorionic surface area in normal and abnormal pregnancies. ●, maternal hypertension; +, normotensive intrauterine growth restriction. *(From Aherne W et al: Quantitative aspects of placental structure,* J Pathol Bacteriol *91:142, 1966.)*

enhanced toward term in ovine placenta (Fig. 14-12), suggesting that permeability and diffusing distance improve as the placenta approaches term. Birthweight has been correlated with placental weight (Fig. 14-13) and with villous surface area (see Fig. 14-11), suggesting that macroscopic and microscopic events are related to optimal placental function.[35,56,62,63]

When placental insufficiency occurs, there may be a functional failure of the placenta as a respiratory or nutritive organ or both. Placental insufficiency associated with maternal nutritional deficiency has more than one effect on fetal growth. In addition to diminished fetal substrate provision, placental metabolism is altered directly, as proposed in Figure 14-9. Diminished placental growth adversely affects total nutrient transfer, whereas reduced placental production of chorionic somatomammotropin attenuates maternal mobilization of fuels to the fetus. Reduced placental energy production and protein synthesis limits active transport of amino acids and facilitative transport of glucose.

When placental insufficiency complicates maternal vascular disease, such as preeclampsia, placental weight and volume also diminish. In addition, a decline in villous surface area (see Fig. 14-11) and a relative increase in nonexchanging tissue occur. At the same time, these placentas show thickening of the capillary basement membrane and increased apoptosis.[63]

A list of additional findings in placental disorders associated with diminished birthweight follows:

Twins (implantation site)
Twins (vascular anastomoses)
Chorioangioma
Villitis (involving toxoplasmosis, other [congenital syphilis and viruses], rubella, cytomegalovirus, and herpes simplex virus [TORCH] association)
Villitis (unknown cause)
Avascular villi
Ischemic villous necrosis
Vasculitis (decidual arteritis)
Multiple infarcts
Syncytial knots
Chronic separation (abruptio placentae)
Diffuse fibrinosis
Hydatidiform change
Abnormal insertion
Fetal vessel thrombosis
Lateral location of implantation (versus anterior or posterior)
Circumvallate placenta
Reduced capillarization
Reduced terminal villus branching
Elevated vascular tone
Increased glucose usage
Confined chromosomal mosaicism (trisomy of 2, 3, 7, 8, 9, 13, 14, 15, 16, 18, 22, or X)
Reduced spiral artery recruitment

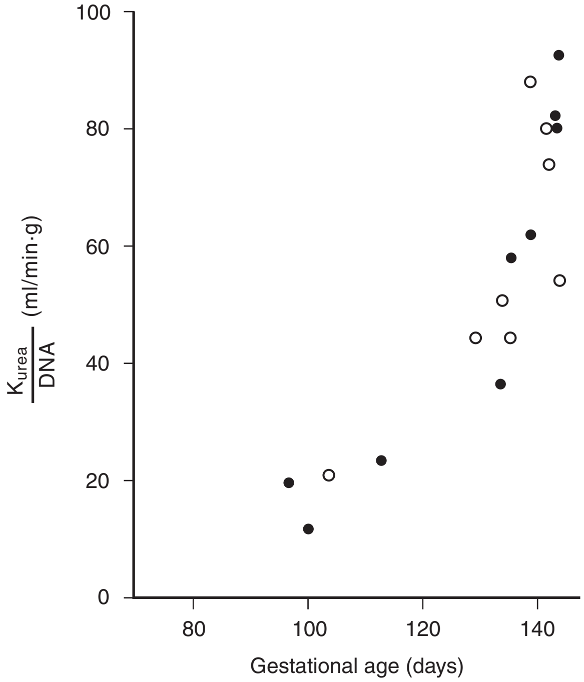

Figure 14–12. Urea permeability per gram of the ovine placenta with increasing gestational age. ●, singletons; ○, twins. *(From Kulhanek J et al: Changes in DNA content and urea permeability of the sheep placenta,* Am J Physiol *226:1257, 1974.)*

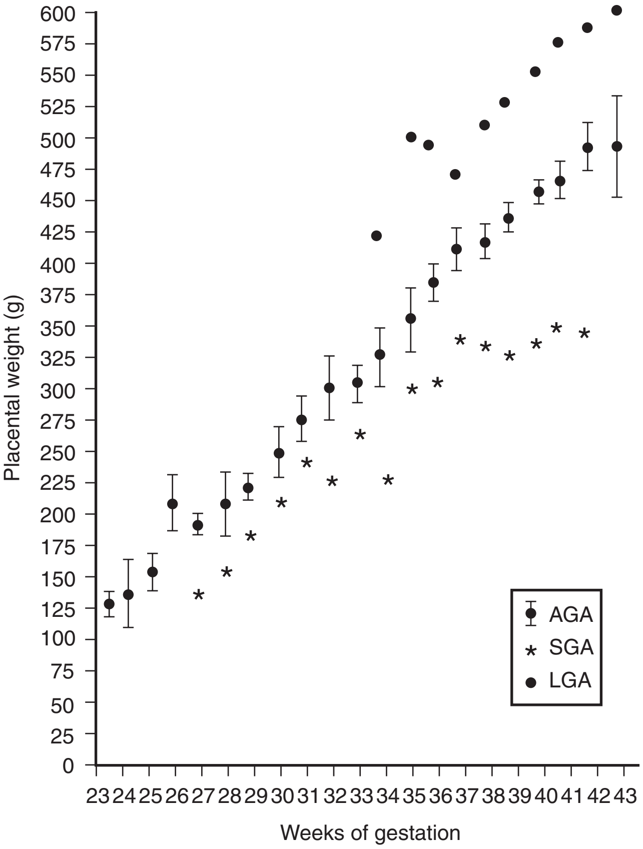

Figure 14–13. Relationship between placental weight and gestational age in neonates. Mean placental weight ± SEM. AGA, appropriate for gestational age; LGA, large for gestational age; SGA, small for gestational age. *(From Molteni R et al: Relationship of fetal and placental weight in human beings,* J Reprod Med *21:327, 1978.)*

Multiple gestations may produce significant placental disorders in suboptimal sites of implantation or, more often, related to abnormal vascular anastomoses in diamniotic monochorionic twinning (Fig. 14-14). As a result of arteriovenous interconnections, one twin serves as the donor and develops IUGR, losing nutrient supplies, whereas the other is the recipient and has satisfactory growth. These anastomoses may be detectable on careful gross examination of the placenta. Ablation of vascular communications in the second trimester, by fetoscopic laser photocoagulation, may reduce the morbidity of the twin-twin transfusion syndrome, which develops in 5% to 17% of monozygotic twins (see also Chapters 19 and 24).

Other detectable potential causes related to aberrant fetal growth include chorioangiomas, large retroplacental infarcts and hemorrhages, abnormal cord insertion patterns, and (questionably) single umbilical artery. Combined reductions of uterine and umbilical blood flow have also been detected in IUGR. Increased vascular resistance has been shown in these circulations. In addition, reduced placental prostacyclin (a potent vasodilator) production may be present in IUGR. Increased placental vascular tone may be fixed or dynamic. The latter may be due to reduced activity of placental nitric oxide synthase or increased circulating fetal levels of angiotensin II or endothelin.

Genetic (genomic or imprinting), enzymatic, and endocrine abnormalities of placental tissue may reduce fetal growth. Decreased expression of enzymes involved in redox regulation (thioredoxin, glutaredoxin) may place placental vessels at risk for endothelial cell oxidative stress and is associated with IUGR. In animals, decreased expression of IGF1R and the insulin receptor produces IUGR. Genes that may regulate nutrient transfer (connexin 2b, *Esx1,* amino acid transporters) are also associated with IUGR in mice.

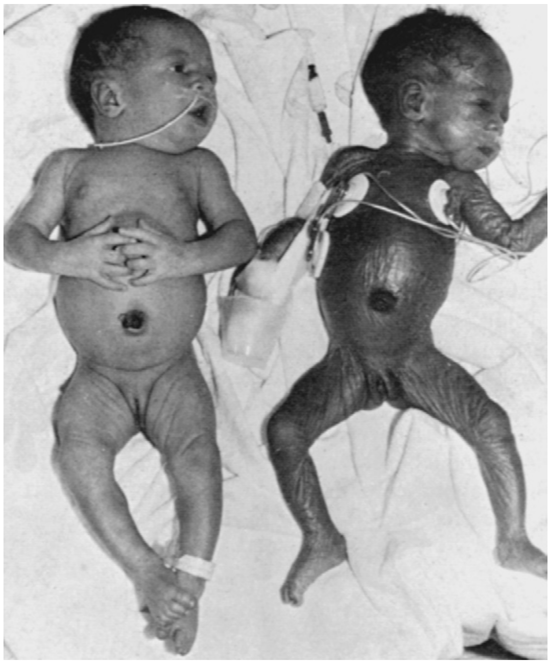

Figure 14–14. Diamniotic monochorionic twins, 36 weeks' gestational age, with birthweights of 2 kg and 1.3 kg.

FETAL DETERMINANTS

Optimal fetal growth depends on adequate provision of substrates, their effective placental transfer, and the inherited regulatory factors within the fetal genotype that affect nutrient use. In addition to substrates, oxygen must be transferred, and an appropriate hormonal milieu must be present. There must also be sufficient room within the uterus. In the absence of adverse environmental effects, the inherent growth potential of the fetus may be achieved.

Genetic determinants of fetal growth are inherited from both parents, and population norms must be established to detect aberrant fetal growth. The average birthweight of Cheyenne Indians is 3800 g at term, whereas that of the Papua New Guinea Luni tribe is 2400 g. Genetic potentials are usually determinants of early fetal growth; nutritional and environmental problems should not affect the fetus until the requirements for tissue growth increase during the third trimester. Reduced first-trimester growth as determined by crown-rump length is a risk factor for IUGR. This risk is even stronger in the presence of increased maternal α-fetoprotein levels.

Approximately 20% of birthweight variability in a given population is determined by the fetal genotype; maternal hereditary and environmental factors contribute an additional 65%; the remaining contributing factors are unknown. Birth order affects fetal size: Infants born to primiparous women weigh less than subsequent siblings. The second child and each additional child weigh an average of 180 g more than the firstborn. This relationship is not true for multiparous adolescent pregnancies, in which subsequent births during adolescence produce neonates with lower term weights than that of the firstborn. Male sex of the fetus is associated with greater birthweight, beginning to become predominant after 28 weeks' gestation. At term, boys weigh approximately 150 g more than girls. A male twin, in addition to affecting its own somatic growth, can also enhance the growth of its female twin. Androgenic hormonal stimulation of fetal growth or paternal imprinting of IGF2 may contribute to these observed differences.

Alternatively, chromosomes may carry growth-determining genes: Genetic material on the Y chromosome may enhance the growth of the male fetus. Similarly, chromosomal deletions or imbalances result in diminished fetal growth. Turner syndrome (XO) is associated with diminished birthweight. The converse is not true: Additional X chromosomes beyond the norm are associated with reduced fetal growth. For each additional X chromosome (in excess of XX), birthweight may be reduced 300 g. Similarly, autosomal trisomies, such as Down syndrome, are also associated with abnormal fetal growth. Chromosomal aberrations often result in diminished fetal growth by interfering with cell division. An intrinsic defect in cultured fibroblasts from patients with trisomy 21 has been observed in tissue culture. Single-gene defects may also reduce fetal growth. The inborn errors most notably associated with diminished fetal weight are listed in Box 14-4. Many syndromes with autosomal recessive, autosomal dominant, polygenetic, or unknown inheritance are also associated with poor fetal growth and occasionally may produce marked IUGR (see also Chapter 29).

BOX 14–4 Disorders Affecting Fetal Growth

CHROMOSOME DISORDERS ASSOCIATED WITH IUGR

Trisomies 8, 13, 18, 21
4p syndrome
5p syndrome
13q, 18p, 18q syndromes
Triploidy
XO
XXY, XXXY, XXXXY
XXXXX

METABOLIC DISORDERS ASSOCIATED WITH DIMINISHED BIRTHWEIGHT

Agenesis of pancreas
Congenital absence of islets of Langerhans
Congenital lipodystrophy
Galactosemia (?)
Generalized gangliosidosis type I
Hypophosphatasia
I-cell disease
Leprechaunism
Maternal and fetal phenylketonuria
Maternal renal insufficiency
Maternal Gaucher disease
Menkes syndrome
Transient neonatal diabetes mellitus

SYNDROMES ASSOCIATED WITH DIMINISHED BIRTHWEIGHT

Aarskog-Scott syndrome
Anencephaly
Bloom syndrome
Cornelia de Lange syndrome
Dubovitz syndrome
Dwarfism (e.g., achondrogenesis, achondroplasia)
Ellis-van Creveld syndrome
Familial dysautonomia
Fanconi pancytopenia
Hallermann-Streiff syndrome
Meckel-Gruber syndrome
Microcephaly
Möbius syndrome
Multiple congenital anomalads
Osteogenesis imperfecta
Potter syndrome
Prader-Willi syndrome
Progeria
Eagle-Barrett (Prune-belly) syndrome
Radial aplasia; thrombocytopenia
Robert syndrome
Robinow syndrome
Rubinstein-Taybi syndrome
Seckel syndrome
Silver syndrome
Smith-Lemli-Opitz syndrome
VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) and VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, esophageal atresia, renal agenesis and dysplasia, and limb defects) syndromes
Williams syndrome
Vanishing twin syndrome

CONGENITAL INFECTIONS ASSOCIATED WITH IUGR

Rubella
Cytomegalovirus
Toxoplasmosis
Malaria
Syphilis
Varicella
Chagas disease

IUGR, intrauterine growth restriction.

Monogenic disorders that affect fetal growth often impair insulin secretion or insulin action.[12] These disorders include reduced fetal insulin secretion by an attenuated insulin-sensing mechanism from a loss of function mutation in the pancreatic glucose-sensing enzyme glucokinase. Reduced insulin action is noted in leprechaunism, which results from a mutation in the insulin receptor. IUGR also has been reported with deletion of the *IGF1* gene. More complicated genetic mechanisms associated with IUGR include maternal uniparental disomy for chromosome 6. Paternal uniparental disomy of chromosome 6 is associated with transient neonatal diabetes and IUGR.

Abnormalities of the epigenetic process, known as *imprinting*, may result in reduced or excessive fetal growth. Epigenetic modification of genes by reversible modification of DNA by methylases and demethylases can suppress gene expression (methylation) in a specific parent (maternal or paternal) of origin without altering the DNA sequence of that gene. Imprinted genes cluster in specific chromosome regions or domains. Imprinting is active in gametogenesis, with different genes being imprinted (methylated, suppressed) depending on the parent of origin. The fertilized egg undergoes a series of DNA demethylations only to be followed by new patterns of methylations in the embryo. Loss of imprinting of the *IGF2* gene results in excessive fetal growth and is noted in certain malignancies (Wilms tumor, colon, ovary). The *IGF2* gene, located at a highly imprinted region (11q15.5), is maternally imprinted (suppressed), but paternally expressed. The normal pattern is that only one allele is expressed (paternal). Biallelic expression predisposes to excessive growth and tumors.

Beckwith-Wiedemann syndrome is a common overgrowth syndrome that illustrates the role of imprinting in the regulation of fetal growth. Beckwith-Wiedemann syndrome is a multigenetic disorder that may be sporadic or familial; cases may also be associated with chromosomal abnormalities in the highly imprinted region at chromosome 11p15.5. Duplication of paternally derived 11p15 and paternal uniparental isodisomy of 11p are noted. Overgrowth may result from overexpression of paternally expressed genes that enhance growth or from suppression of maternally expressed genes that inhibit growth. Many sporadic cases of Beckwith-Wiedemann syndrome exhibit biallelic expression (normal is expression of the paternally derived gene only, as the maternal gene is imprinted and suppressed) of the *IGF2* gene.[10,26]

Because imprinting through methylation and demethylation is quite active during gametogenesis and embryogenesis, there may be alterations in the pattern of differentially expressed genes during various assisted reproductive technologies. Infants born after assisted reproductive technologies have a higher incidence of potential imprinting disorders such as Beckwith-Wiedemann syndrome, Angelman syndrome, and retinoblastoma.[37,59]

Additional disorders resulting partly from imprinting errors include uniparental disomy for chromosome 7 with IUGR, 10% of Silver-Russell syndrome, and transient neonatal diabetes. An imprintable gene possibly involved in Silver-Russell syndrome, *GRB10,* codes for growth factor receptor binding proteins that interact with the insulin and IGF receptors.

Infectious agents are typically sought as being responsible for early onset of IUGR. Cytomegalovirus and rubella virus are the most important identifiable agents associated with marked fetal growth restriction. After maternal viremia, both agents invade the placenta, producing varying degrees of villitis, and subsequently gain access to fetal tissues. The effects of placentitis itself on fetal growth are unknown, but when congenital fetal infection has occurred, these viral agents have direct adverse effects on fetal development. Intracellular rubella virus inhibits cellular mitotic activity in addition to producing chromosomal breaks and subsequently cytolysis. In addition, this virus produces an obliterative angiopathy that compromises cell viability further. Cytomegalovirus also causes cytolysis, resulting in areas of focal tissue necrosis. These viral agents reduce cell number and subsequent birthweight by simultaneously inhibiting cell division and producing cell death (see also Chapters 23 and 39). Box 14-4 contains examples of disorders affecting fetal growth.

INFANTS WITH INTRAUTERINE GROWTH RESTRICTION AND SMALL FOR GESTATIONAL AGE

Definition

An infant with low birthweight (less than 2500 g) is not always premature (earlier than 37 weeks). Worldwide, more than 20 million infants are born weighing less than 2500 g. Of these infants, 30% to 40% are born at term gestation and are undergrown (SGA status). Population norms need to be determined for each specific genetic group, especially groups characterized by unusual inherited patterns of fetal growth. Generally, these population norms established in various North American and European cities describe the usual fetal growth pattern for industrial societies and may be used as the reference norms for similar ethnic groups (see Fig. 14-1 and Table 14-1). Each curve defines either standard deviations or percentile units that include the normal variability or distribution of birthweights at each gestational age. By definition, infants less than 2 standard deviations or infants at less than the 3rd percentile (10th percentile for Denver curves because of the lower birthweight at higher altitudes) are classified as SGA. Of each population, 2.5% to 10% has SGA status.

The use of population means can be misleading. Within a sibship, birthweight is less variable and more consistent than that for an entire population. Compared with family members, 80% of infants with congenital rubella infection were classified as SGA, whereas only 40% were SGA when population standards were used. Fetal growth assessment must be considered in the context of prior reproductive history and clinical examination of the newborn.

Infants with IUGR may or may not be SGA. Alternatively, infants who are SGA may not have been affected by growth-restricting processes that produce IUGR. Weight parameters at birth may be insensitive in determining IUGR. The ponderal index (weight divided by length cubed) or other body proportion ratios (head circumference to weight or length, femur length to abdominal circumference, head circumference to abdominal circumference) may be useful in detecting additional cases of IUGR during the fetal or neonatal period. IUGR resulting from placental insufficiency usually reduces birthweight more than length, and to a greater degree than head circumference, and it would be evident by a reduced ponderal index with a smaller, albeit relatively large (spared), head circumference. The greater the severity of IUGR, the greater is the deviation of weight, length, and (less so) head circumference from gestational age norms. Alterations of body proportion ratios may create a continuum rather than a dichotomous classification of birthweight status (appropriate for gestational age [AGA] versus SGA).

Deviations of fetal weight from a predetermined genetic potential produce IUGR with or without SGA status. Second-trimester fetal anthropometric and biometric ultrasonography can be used to predict an ideal weight, which may be modified by intrinsic and extrinsic growth-limiting factors. Any variation from the predicted weight would be considered IUGR. The growth potential realization index assesses deviations from norms of weight and of head, abdominal, and thigh circumferences. This index is applied to the infant after birth by calculating a neonatal growth assessment score that includes the deviation of each growth parameter from its related normative value for that gestational age. A neonatal growth assessment score of 0 indicates ideal growth, and scores greater than 20 indicate IUGR, but not SGA.

Aberrant Fetal Growth Patterns

Fetal growth restriction may originate early or late during fetal development. Approximately 20% of all infants who are SGA show reduced fetal growth early in gestation. Infants may be symmetrically growth restricted: Head circumference, weight, and length are proportionately affected to equivalent degrees. These fetuses and infants continue to grow, albeit with reduced net effect (Fig. 14-15A). In addition to inherent genetic growth constraint, other factors may produce diminished growth potential in these neonates. Congenital viral infections usually have their worst effect if infection occurs during the first trimester, when they have a significant effect on cell replication and subsequently on birthweight. Similarly, abnormal genetic factors, such as single gene deletions and chromosomal disorders, also reduce the intrauterine growth rate at an early stage of development. Very early onset of growth delay has been reported in anomalous infants of diabetic mothers.

Later onset of growth restriction is usually associated with impaired uteroplacental function or nutritional deficiency during the third trimester (see Fig. 14-15B). Nutrient supplies, oxygen, and uteroplacental perfusion are in excess of their requirements during early fetal development and should not interfere with fetal growth until the growth rate exceeds the provision of substrates or oxygen or both. During the last trimester, the fetal growth rate and net tissue accretion increase markedly; if the uteroplacental supply line is compromised, IUGR develops.

The anthropometric findings among these infants show a relative sparing of head growth, whereas body weight and somatic organ growth are more seriously altered. Spleen, liver, adrenal, thymus, and adipose tissue growth is affected to the greatest extent in newborns who are SGA owing to a later onset (Figs. 14-16 and 14-17). The relative sparing of fetal head (brain) growth is caused by preferential perfusion of the brain with well-oxygenated blood containing adequate substrates after redistribution of the cardiac output during periods of fetal distress. Infants with IUGR resulting from unknown or nutritional causes may have successfully adapted to a “hostile” in utero environment with reduced growth. After birth, in a more favorable environment, catch-up growth ensues.

Antenatal Care

DIAGNOSIS

Antenatal diagnosis of IUGR has proved difficult.[3,15,30,53] Many of these infants deliver at or beyond term without prior antenatal detection. At best, when sought with careful maternal physical examination, accurate dating, and risk-assessment analysis, only 50% of these infants may be identified by clinical examination before birth. Antenatal detection is an essential component of care for these infants because they require intensive obstetric and neonatal management to reduce their excessive perinatal morbidity and mortality rates. This poor outcome is associated with unexplained antepartum or intrapartum fetal death, neonatal asphyxia, and major neonatal adaptive problems. Neonatal risks are increased at each gestational age, but highest if the fetus is also preterm. Antenatal identification and intensive perinatal care of the mother, the fetus, and, later, the neonate are imperative components that result in improved outcome for these infants.

Careful measurement and recording of fundal height at each antenatal visit are reasonable clinical screening aids in the diagnosis of IUGR. When dates are confirmed by onset of quickening, audible heart tones, and accurate menstrual history, size-date discrepancy (i.e., fundal height less than or lagging behind the norm for gestational age) suggests IUGR. History findings that may be components of a risk assessment score for IUGR include a history of a previous infant who was SGA, vaginal bleeding, multiple gestation, low prepregnancy weight, and poor pregnancy weight gain. Chronic maternal

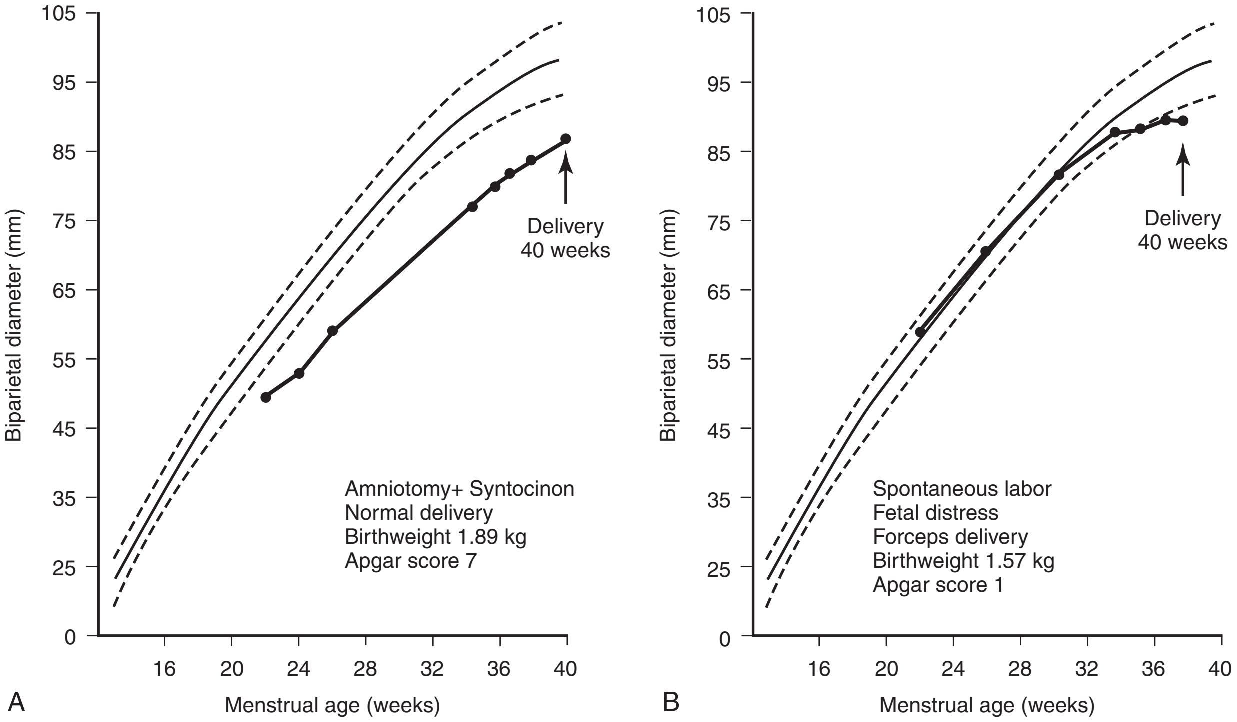

Figure 14–15. A and B, Low-profile (A) and late-flattening (B) patterns of intrauterine growth restriction. *(From Campbell S: Fetal growth. In Beard R et al, editors:* Fetal physiology and medicine, *Philadelphia, 1976, Saunders, p 271.)*

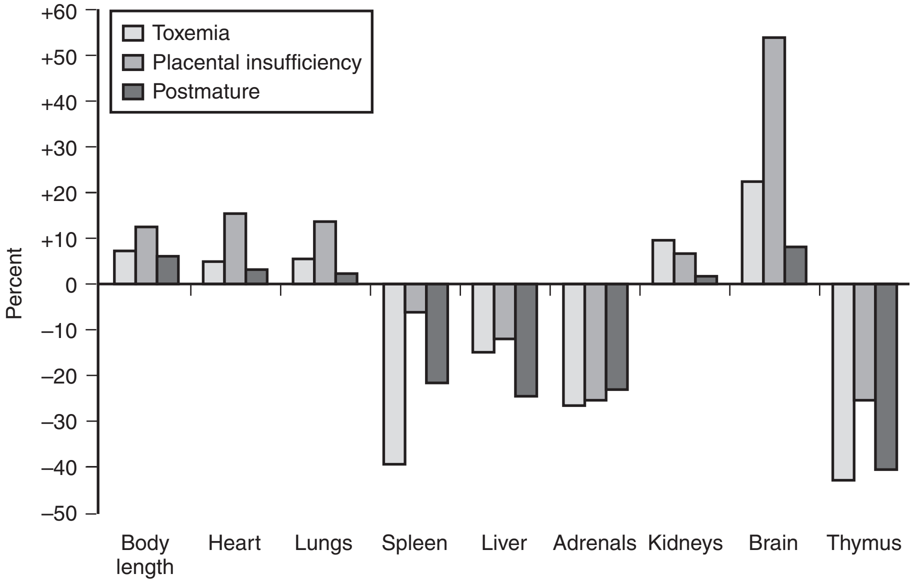

Figure 14–16. Deviation of organ weights after intrauterine growth restriction. *(From Naeye R et al: Judgment of fetal age, 3: the pathologist's evaluation,* Pediatr Clin North Am 13*:849, 1966.)*

illness and preeclampsia are also high-risk situations indicating possible IUGR.

Laboratory tests, including determination of maternal serum estriol level, placental lactogen, and various pregnancy-associated proteins, have been unreliable markers for IUGR. The diagnosis of chronic fetal distress in the absence of obvious alterations of fetal heart rate patterns is now possible with cordocentesis (percutaneous umbilical blood sampling). Although not indicated for all patients with IUGR, fetal blood sampling may show hypoxia, lactic acidosis, hypoglycemia, and normoblastemia caused by chronic fetal distress. Hypoxia may precede fetal acidosis. Fetal blood sampling may also permit rapid karyotyping of a fetus with IUGR with malformations and the identification of TORCH infections through the assessment of antibody titers, culture, or DNA diagnosis of TORCH agents.

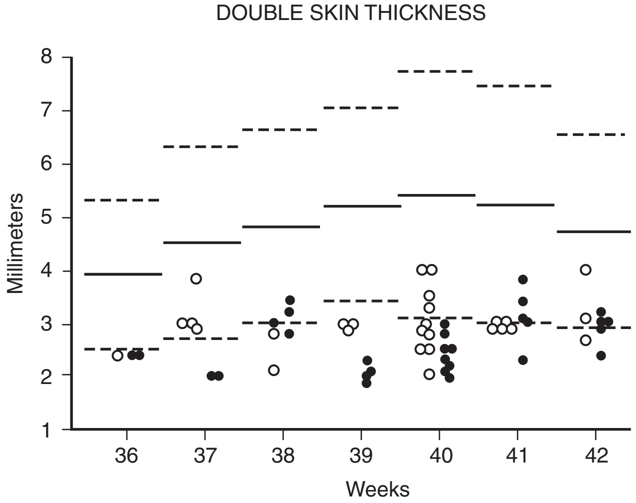

Figure 14–17. Skinfold thickness is a major determinant of neonatal subcutaneous fat deposits. Fetal malnutrition with (●) and without (○) severe clinical signs of wasting. *(From Usher R: Clinical and therapeutic aspects of fetal malnutrition,* Pediatr Clin North Am *17:169, 1970.)*

Ultrasound assessment of the fetus can help detect the presence of IUGR.[3,30,45,46,53,64] Used as either a routine two-step process (dating/sizing in mid-second trimester; follow-up assessment at 32 to 34 weeks) or based on risk analysis, fetal ultrasonography is the primary method for identifying fetuses with IUGR. Ultrasonography includes real-time biometric and anthropomorphic analysis of fetal growth parameters (head circumference, biparietal diameter, transcerebellar diameter, abdominal circumference, femur length), detection of anomalies, and identification of oligohydramnios.[40] Oligohydramnios is a risk factor for congenital anomalies, severe IUGR with reduced urine production, pulmonary hypoplasia, variable decelerations from cord compression, and intrauterine fetal death in 5% to 10% of affected fetuses. The risk of congenital anomalies with oligohydramnios increases from 1% to 9% with mild-to-severe amniotic fluid deficits; at the same time, the risk of IUGR increases from 5% to 40%.

The degree of oligohydramnios can be determined on ultrasound and quantitated by means of the four-quadrant amniotic fluid index. The vertical diameters of four pockets of amniotic fluid are added to determine the amniotic fluid index. Between 26 and 38 weeks of gestation, the amniotic fluid index is 12.9 ± 4.6 cm; an index of less than 5 cm signifies severe oligohydramnios.

Morphometric analysis of fetal growth parameters includes determination of serial biparietal diameters as analyzed by absolute number and rate of change (see Fig. 14-15). Head sparing in asymmetric IUGR may make fetal measurements of the biparietal diameter less sensitive; however, truncometry—measuring the fetal abdominal circumference (in part, liver size) at the level of the umbilical vein—may add accuracy (Fig. 14-18). Using ratios of fetal growth parameters and adding the femur length or the transcerebellar diameter and the fetal ponderal index may increase the sensitivity of fetal biometry.

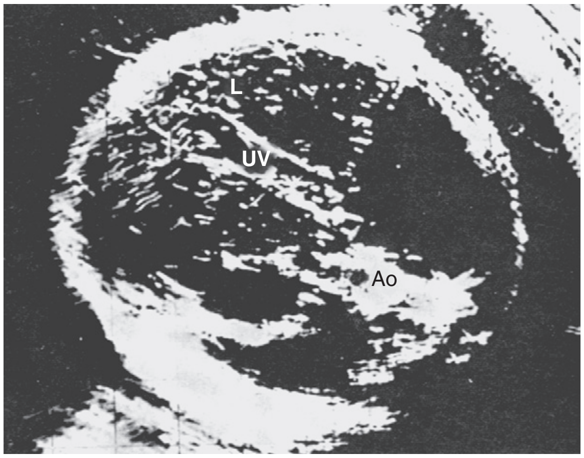

Figure 14–18. Truncometry at the level of fetal liver (L), umbilical vein (UV), and aorta (Ao). (*From Campbell* S: Size at birth, *Amsterdam, 1974, Elsevier Scientific.)*

Doppler flow velocity waveforms, assessed in the maternal and fetal circulations, may detect increased maternal and fetal vascular resistance before the onset of IUGR (Fig. 14-19).[3,30,45,46,53,64] Maternal arcuate arterial flow may reflect trophoblastic invasion of the myometrium because increased flow may be associated with increased vascular invasion and better placental perfusion. Alternatively, decreased maternal arcuate arterial waveform velocity may show increased maternal vascular resistance and decreased uteroplacental perfusion. Uterine vessel velocimetry is less accurate than waveforms in fetal vessels in predicting IUGR and fetal hypoxia.

Chronic fetal distress with hypoxia (with or without acidosis) is associated with fetal Doppler arterial waveform velocities that indicate reduced systemic (descending aorta, umbilical artery) flow and normal or increased cerebral (middle cerebral artery) flow (head sparing). The greatest risk is associated with absent or, even more seriously, with reversed diastolic flow in the umbilical artery. Absent end-diastolic velocimetry may be stable, or it may progress to reversed flow; both indicate placental insufficiency. Reversed flow greatly increases fetal risk and is usually unstable and requires consideration for delivery. If other features are otherwise normal (biophysical profile, amniotic fluid volume, reassuring cardiotocograms, minute-to-minute variation), steroids can be given, and delivery can be temporarily delayed.

Assessment of the fetal middle cerebral artery may show centralization in the compromised fetus, showing increased flow in the middle cerebral artery relative to the placenta. Preservation of middle cerebral artery diastolic flow may be seen with absent or sometimes reversed flow in the umbilical artery. Decreased middle cerebral artery flow is associated with fetal cardiac decompensation and is an ominous sign. Umbilical venous pulsation or dilation of the ductus venosus and reversed flow in the vena cava also suggests serious cardiac compromise from hypoxia or anemia. Abnormalities on the venous side of the circulation occur later than in the umbilical arteries.

Figure 14–19. Doppler velocimetry of fetal vessels. *Upper panel,* normal umbilical artery flow waveform. *Middle panel,* normal waveform of the middle cerebral artery. *Lower panel,* abnormal ductus venosus waveform, showing a reversed wave. *(From Odibo AO, Sadovsky Y: Diagnosis and management of in utero/ growth failure. Kiess W et al, editors: Small for gestational age: causes and consequences, Pediatr Adolesc Med 13:11, 2009.)*

The progression of fetal cardiovascular compromise usually begins with abnormal pulsatility indexes in the umbilical artery or middle cerebral artery followed by abnormal peak systolic velocity in the middle cerebral artery with absent or reversed diastolic flow in the umbilical artery, and the presence of umbilical vein or ductus venosus pulsations. In the most serious progression of fetal compromise, there is reversed flow in the ductus venosus or umbilical vein and an abnormal tricuspid valve E/A wave ratio and valve regulation.[45] Delivery should be considered if there is reversal of umbilical artery end-diastolic flow and the fetus is 32 weeks or greater, or if there is absent umbilical artery diastolic flow at greater than 34 weeks.[45]

ANTENATAL MANAGEMENT

When the diagnosis of IUGR is suspected and strengthened by ultrasonography, it is essential to institute appropriate maternal and fetal care and closely monitor the well-being of the fetus (see also Chapter 10).[25,30,46] With severe IUGR, maternal activity should be limited, and bed rest should be initiated, with the mother assuming a left lateral recumbent position to ensure optimal uterine blood flow. Administration of oxygen to the mother has resulted in improved fetal oxygenation, some growth, and normalization of fetal aortic blood flow velocity in some fetuses with IUGR and chronic fetal distress.

Assessment of fetal well-being should begin when the diagnosis is suspected and the fetus has approached a gestational age compatible with extrauterine survival. An inexpensive screening tool is a log of fetal activity recorded by the mother; normal activity is a reasonable sign of well-being. A specific period should be monitored, such as after a meal, and fetal activity should be recorded each day. In addition to this maternal record, a systematic approach to fetal evaluation should be performed routinely and frequently.

Classically, the oxytocin challenge test (OCT) has been used to predict the potential for fetal death or acute intrapartum death in a marginally oxygenated, compromised fetus. This test requires the intravenous administration of oxytocin, which must result in three uterine contractions within 10 minutes. Late decelerations denote relative uteroplacental insufficiency and suggest that the oxygenation of the fetus may be impaired. A positive OCT result (three late decelerations with three contractions) also suggests that the fetus may not tolerate the contractions that occur during labor. This is not a universal observation; a significant percentage of these infants may be able to withstand spontaneous or oxytocin-induced labor without the development of fetal acidosis. Fewer decelerations than those for a positive OCT result should be considered suspect, and the test should be repeated (along with technically unsatisfactory tracings) within the next 24 to 48 hours.

Because technical and time difficulties are related to the OCT, and because contraindications exist for its use, such as a previous classic cesarean section, placenta previa, and concern about inducing premature labor, the nonstress test (NST) has been employed. The NST examines fetal well-being by determining the acceleration of the fetal heart rate after spontaneous fetal movement. A healthy fetus (nonhypoxic) responds to its own body movements with a mean acceleration of 15 beats/min above the baseline heart rate. In addition, the frequency of fetal movements should be ascertained; at the same time, examination of beat-to-beat and long-term variability can offer additional useful information. The NST can also supplement the OCT because fetuses with a positive OCT result but a reactive NST result and normal beat-to-beat variability are more likely to tolerate labor without untoward problems. Under stable maternal conditions and with signs of fetal well-being (negative OCT result or reactive NST result or both), these tests may be repeated weekly.

The false-positive rate for OCT (25%) and NST (20%) is high compared with the false-negative rate for OCT (0.4 in 1000) and NST (6.8 in 1000). The rate of intrauterine fetal death is high after a positive OCT result (32%), but lower with a nonreactive NST result (12%). The contraction stress test is more predictive of fetal death and has fewer false-negative results. More false positive results are obtained than with the NST, however.

Biophysical determinants have been used successfully to assess fetal well-being. The combined analyses of fetal breathing movements, gross body movements, fetal tone, fetal heart reactivity to movement, and qualitative amniotic fluid volume have improved the antenatal management of IUGR (Table 14-6). This biophysical profile provides a nonweighted score that can identify the fetus at risk. A biophysical profile

TABLE 14–6 Biophysical Profile Scoring: Technique and Interpretation*

Biophysical Variable	Normal (Score = 2)	Abnormal (Score = 0)
Fetal breathing movements	≥1 episode of ≥30 s in 30 min	Absent or no episode of ≥30 s in 30 min
Gross body movements	≥3 discrete body or limb movements in 30 min (episodes of active continuous movement considered as single movement)	≤2 episodes of body or limb movements in 30 min
Fetal tone	≥1 episode of active extension with return to flexion of fetal limb(s) or trunk (opening and closing of hand considered normal tone)	Slow extension with return to partial flexion or movement of limb in full extension or absent fetal movement
Reactive fetal heart rate	≥2 episodes of acceleration of ≥15 beats/min and of ≥15 s associated with fetal movement in 20 min	<2 episodes of acceleration of fetal heart rate or acceleration of <15 beats/min in 20 min
Qualitative amniotic fluid volume	≥1 pocket of fluid measuring ≥1 cm in 2 perpendicular planes	Either no pockets or a pocket of <1 cm in 2 perpendicular planes

*See Manning FA et al: Antepartum fetal evaluation: development of a biophysical profile, *Am J Obstet Gynecol* 136:787, 1980.
Modified from Manning FA et al: Fetal assessment based on fetal biophysical profile scoring, *Am J Obstet Gynecol* 151:343, 1985.

score of 8 to 10 carries a 0.8% chance of fetal death, whereas a score of 0 predicts a fetal mortality rate of 40%. This analysis takes approximately 30 minutes and should be repeated weekly with scores of 8 to 10. If the score is less than 8, the biophysical profile should be repeated that afternoon. If the score is again less than 8, an OCT should be performed, and a decision should be made to deliver the infant, regardless of gestational age, unless severe anomalies are determined.

A low biophysical profile correlates with fetal hypoxia determined by cordocentesis. Assessment of fetal aortic flow with the pulsatile index may also help determine optimal timing for delivery. If fetal lung maturity is present, aortic blood flow is reduced, and there is other evidence of fetal distress, the fetus may need to be delivered before term. Factors that affect the biophysical profile score include sedation, stimulants (cocaine, theophylline), indomethacin (decreases amniotic fluid), cigarette smoking (decreases fetal breathing movements), hyperglycemia (increases fetal breathing movements), and hypoglycemia (decreases all activities).

The mode of delivery is not dictated by the abnormalities recorded by biophysical or electrophysiologic surveillance of the fetus. Some patients can tolerate labor after a positive OCT result, with oxygen administration and a left lateral recumbent position. It would be judicious to avoid labor, however, in situations complicated by a nonreactive NST result, a flat baseline, absent or reversed diastolic flow, and a positive OCT result. Similarly, premature infants who are SGA, in particular infants with a breech presentation and infants whose mothers have a completely unfavorable cervix, should be delivered by the abdominal route. Particular attention should be given to an asymmetrically (late-flattening) growth-restricted fetus with chronic fetal distress who tolerates labor poorly and readily develops signs of acute fetal distress compared with a symmetrically undergrown fetus and a normal fetus.

Whether labor is induced or spontaneous, continuous intrapartum fetal heart rate monitoring combined with appropriate use of fetal scalp pH determinations and fetal pulse oximetry should be employed (see also Chapter 10). If late decelerations become evident, scalp blood pH might be evaluated, and if fetal acidosis has developed, delivery should be expedited. Whether to deliver early or late has not been resolved, but early (preterm) delivery is associated with neonatal mortality, whereas late delivery is associated with intrauterine fetal demise.[36,46]

During labor, uterine contractions may compromise marginal placental perfusion and fetal gas exchange further. The myocardium of these fetuses may have diminished glycogen stores, a key energy source partially responsible for the fetal ability to withstand asphyxia. Because there is a high incidence of intrapartum birth asphyxia, it is essential that the delivery be coordinated with the neonatal team, which should be prepared to resuscitate a depressed or asphyxiated neonate. In addition, combined obstetric-pediatric management is indicated if meconium is present in the amniotic fluid. This event often follows periods of fetal hypoxia and stress, occurring with greatest frequency in a term or postterm neonate who is SGA.

Obstetric management should include oropharyngeal suctioning immediately after delivery of the head. Immediately after birth, the neonatal team should clear the oropharynx further, and possibly also the trachea, of additional meconium (see also Chapter 44, Part 5). Saline amnioinfusion may be beneficial in the presence of oligohydramnios and an amniotic fluid index of less than 5 cm. Titration to an index of greater than 8 cm may reduce the incidence of meconium-stained fluid, variable decelerations, end-stage bradycardia, fetal distress, and acute fetal acidosis.

APPROACH TO AN INFANT WHO IS SMALL FOR GESTATIONAL AGE

After birth, an infant who is SGA may develop significant neonatal problems (Table 14-7).[24,41,61,73] In the delivery room, it is essential to ensure optimal neonatal cardiopulmonary physiologic adaptation, while ensuring minimal heat loss in a warm environment. When stabilization has been established, a careful physical examination should be performed.

When infants with obvious anomalies and syndromes and infants born to mothers with severe illness or malnutrition are excluded, there still remains a heterogeneous population of infants who are SGA. These infants have a characteristic physical appearance: The head looks relatively large for the undergrown trunk and extremities, which seem wasted. The abdomen is scaphoid. The extremities have little subcutaneous tissue or fat, which is best exemplified by a reduced skinfold thickness (see Fig. 14-17). The skin appears to hang; it is rough, dry, and parchment-like; and it desquamates easily. Fingernails may be long, and the hands and feet of the infant tend to look too large for the rest of the body. The facial appearance suggests the look of a “wise old person,” especially compared with that of premature infants (Fig. 14-20). Cranial sutures may be widened or overriding; the anterior fontanelle is larger than expected, representing diminished membranous bone formation. Similarly, epiphyseal ossification at the knee (chondral bone) is also delayed. Decreased bone mineralization may be present. When meconium is passed in utero, there is often yellow-green staining of the nails, skin, and umbilical cord, which may also appear thinner than usual.

Gestational age assessment of an infant who is SGA may result in misleading data when based on physical criteria alone. Vernix caseosa is frequently reduced or absent as a result of diminished skin perfusion during periods of fetal distress or because of depressed synthesis of estriol, which enhances vernix production. In the absence of this protective covering, the skin is continuously exposed to amniotic fluid and begins to desquamate after birth. Sole creases are determined partly by exposure to amniotic fluid and appear more mature. Breast tissue formation also depends on peripheral blood flow and estriol levels and becomes markedly reduced in infants who are SGA. In addition, female external genitalia appear less mature because of the absence of the perineal adipose tissue covering the labia. Ear cartilage may also be diminished.

Neurologic examination for gestational age assessment may be affected less by IUGR than the physical criteria. Infants with IUGR achieve appropriate neurologic maturity functionally. Peripheral nerve conduction velocity and visual-evoked or auditory-evoked responses correlate well with gestational age in normal neonates and are not impaired after IUGR. These aspects of neurologic maturity are not sensitive to deprivation, and occasionally maturity may become accelerated. Determinants of active or passive tone

TABLE 14–7 Problems of Neonates Who Are Small for Gestational Age

Problem	Pathogenesis	Assessment/Prevention/Treatment
Fetal death	Placental insufficiency, chronic fetal hypoxia	Biophysical profile Vessel velocimetry Cordocentesis Maternal O_2 Early delivery
Asphyxia	Acute fetal hypoxia superimposed on chronic fetal hypoxia, acidosis Placental insufficiency ↓ cardiac glycogen stores	Antepartum and intrapartum monitoring Efficient neonatal resuscitation
Meconium aspiration pneumonia	Hypoxic stress	Pharyngeal-tracheal aspiration
Fasting hypoglycemia	↓ hepatic glycogen ↓ gluconeogenesis ↓ counter-regulatory hormones Cold stress Asphyxia-hypoxia	Early oral or intravenous alimentation or both
Alimented hyperglycemia	"Starvation diabetes"	Glucose infusion not to exceed 8 mg/kg/min except with hypoglycemia Consider insulin if transient or permanent neonatal diabetes mellitus; consider insulin resistance at receptor or postreceptor level
Polycythemia/hyperviscosity	Placental transfusion Fetal hypoxia Erythropoietin	Neonatal partial exchange transfusion
Temperature instability	Cold stress Poor fat stores Catecholamine depletion Hypoxia, hypoglycemia Reduced fasting O_2 consumption	Neutral thermal environment Early alimentation
Dysmorphology	TORCH Syndrome complexes Chromosome disorders	Disease-specific therapy or prevention
Teratogen exposure		Disease-specific therapy or prevention
Pulmonary hemorrhage (rare)	Hypothermia, polycythemia Hypoxemia/DIC	Avoid cold stress, hypoxia Endotracheal administration of epinephrine PEEP
Immunodeficiency	"Malnutrition" effect TORCH	Unknown Specific therapy if available
Decreased bone mineral density	Possible substrate deficiency or altered vitamin D metabolism	Appropriate postnatal oral calcium and vitamin D intake

DIC, disseminated intravascular coagulation; PEEP, positive end-expiratory pressure; TORCH, toxoplasmosis, other (e.g., congenital syphilis and viruses), rubella, cytomegalovirus, and herpes simplex virus association.

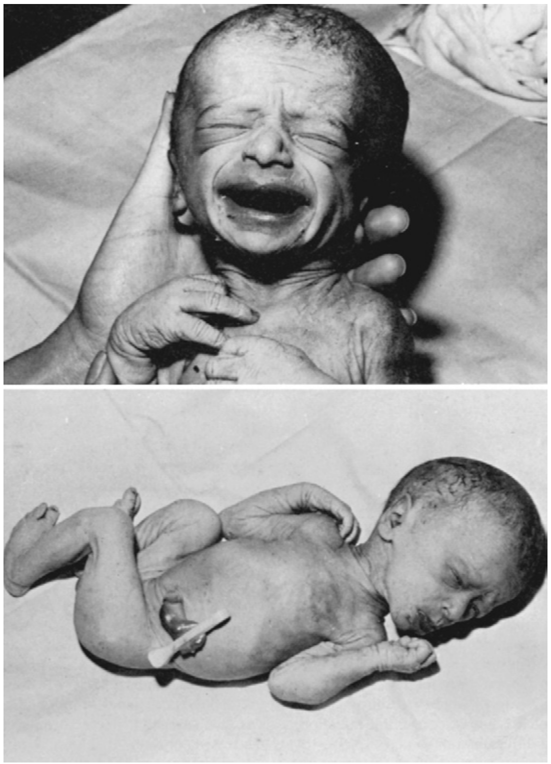

Figure 14–20. Term infant who is small for gestational age (birthweight 1500 g), with wizened facies and dry, desquamating, hanging skin.

and posture may be reliable in infants who are SGA, assuming that infants with significant central nervous system (CNS) disorders (anomalies, asphyxia) and metabolic disorders (hypoglycemia) are excluded.

Specific organ maturity occurs despite diminished somatic growth. Cerebral cortical convolutions, renal glomeruli, and alveolar maturation all relate to gestational age and are not growth restricted with IUGR. As a result of stress in utero, these infants occasionally may have accelerated maturity of specific organ systems, such as the lung, explaining the lower incidence of respiratory distress syndrome in some preterm neonates who are SGA.

When examined in closer detail, infants who are SGA exhibit specific behavioral characteristics that suggest, despite electric neurologic maturity, that functional CNS maturity may be impaired. In the absence of significant CNS disease, these neonates exhibit abnormal sleep cycles and diminished muscle tone, reflexes, activity, and excitability. This hypoexcitability suggests an adverse effect on polysynaptic reflex propagation and implies that CNS functional maturity does not proceed independently of the intrauterine events that result in IUGR.

When stabilized and assigned a gestational age, a neonate who is SGA should be examined in more detail to direct the diagnostic workup as outlined:

A. History and physical examination
B. Accurate growth parameters plotted on appropriate (for disease or ethnicity) growth curves and gestational age determination
C. Findings
  1. Dysmorphic features suggesting
    a. Chromosome abnormality
    b. Syndrome
    c. Drugs (fetal exposure)
  2. Blueberry-muffin rash, petechiae, hepatosplenomegaly, and ocular (cornea, lens, retina) pathologic changes suggesting
    a. Rubella
    b. Cytomegalovirus
    c. Other congenital infection
  3. Neither 1 nor 2 present suggests
    a. Chronic fetal hypoxia
    b. Constitutional factors
    c. Genetic factors
    d. Nutritional factors
    e. Toxins
    f. Placenta insufficiency
    g. Undetermined

Dysmorphic features; "funny-looking" facies; and abnormal hands, feet, and palmar creases, in addition to gross anomalies, suggest congenital malformation syndromes, chromosomal defects, or teratogens. Ocular disorders, such as chorioretinitis, cataracts, glaucoma, and cloudy cornea, in addition to hepatosplenomegaly, jaundice, and a blueberry-muffin rash, suggest a congenital infection (see also Chapters 23 and 39).

The remaining infants constitute a heterogeneous group that represents most neonates who are SGA. Multiple gestations are the most recognizable cause in this category. TORCH infections resulting in extremely low birthweight are unusual in the absence of other clinical signs of congenital infection; however, a screening determination on cord blood for IgM values and a urine culture for cytomegalovirus may be indicated. In addition, radiographic examination of the long bones, together with ultrasonography of the head, is diagnostically useful. Careful data related to the present and past reproductive history of the mother, in addition to ongoing neonatal management and close observation, are indicated in the remaining numerous neonates who are SGA whose underlying disorders may never be determined.

NEONATAL PROBLEMS

The perinatal mortality rate in infants who have IUGR is 10 to 20 times that in infants who are AGA. Intrauterine fetal death from chronic fetal hypoxia, immediate birth asphyxia, the multisystem disorders associated with asphyxia (hypoxic-ischemic encephalopathy, persistent pulmonary hypertension, cardiomyopathy), and lethal congenital anomalies are the main contributing factors to the high mortality rate for fetuses and neonates who have IUGR. Problems resulting from prematurity, such as respiratory distress syndrome, are more common with IUGR. Neurologic and other morbidities are also more frequent in infants who have IUGR; they have a rate 5 to 10 times that of infants who are AGA. Most intrauterine fetal deaths occur between 38 and 42 weeks' gestation and can be potentially avoided by careful assessment and intervention.

ASPHYXIA

Perinatal asphyxia and its sequelae constitute the most significant immediate problem of infants who have IUGR. Uterine contractions may add an additional hypoxic stress on a chronically hypoxic fetus with a marginally functioning placenta. The ensuing acute fetal hypoxia, acidosis, and cerebral depression may result in fetal death or neonatal asphyxia. IUGR accounts for a large proportion of stillborn infants. Myocardial infarction, amniotic fluid aspiration, and signs of cerebral hypoxia are noted in stillborn infants with IUGR. With repeated episodes of fetal asphyxia or persistent hypoxemia, myocardial glycogen reserves are depleted, further limiting the fetal cardiopulmonary adaptation to hypoxia. If inadequate resuscitation occurs at birth, and Apgar scores are low, the combination of intrapartum and neonatal asphyxia places the infant in double jeopardy for a continuum of CNS insult.

The sequelae of perinatal asphyxia include multiple organ system dysfunction potentially characterized by hypoxic-ischemic encephalopathy, ischemic heart failure, meconium aspiration pneumonia, persistent pulmonary hypertension gastrointestinal perforation, and acute tubular necrosis. Concomitant with these sequelae, there may be metabolic derangements, such as hypoglycemia. Hypocalcemia is partly caused by excessive phosphate release from damaged cells or acidosis; it is exacerbated by sodium bicarbonate and diminished calcium intake. Hypocalcemia does not occur more often with IUGR unless these problems are present. Meconium aspiration syndrome may complicate the clinical picture and compromise respiratory function and oxygenation further with the development of pneumonitis and pneumothorax.

NEONATAL METABOLISM

Fasting hypoglycemia develops in infants who are SGA more than in any other neonatal subgroup or category. The propensity for hypoglycemia is greatest during the first 3 days of life. Key to the occurrence of hypoglycemia is the diminished hepatic glycogen stores (Fig. 14-21). Glycogenolysis constitutes the predominant source of glucose for the neonate during the immediate hours after birth. Later in the day, when glycogen stores become depleted, fasting glucose production results from the incorporation of lactate and gluconeogenic amino acid precursors into glucose. Infants who are SGA exhibit an inability to increase blood glucose concentration after oral or intravenous administration of alanine, the key gluconeogenic amino acid.[20] Hypoglycemic infants who are SGA have elevated alanine and lactate levels, suggesting that substrate availability is not rate limiting for gluconeogenesis, but the enzymes or cofactors are inactive. Hypoglycemic infants probably have reduced hepatic glucose production. Nonhypoglycemic infants who are SGA show rates of gluconeogenesis from alanine that are equivalent to the rates seen in nonhypoglycemic neonates who are AGA.

Immediately after birth, fasting infants who are SGA may have lower plasma-free fatty acid levels than normally grown infants. Fasting blood glucose levels in infants who are SGA directly correlate with free fatty acid and ketone body levels in plasma. In addition, infants who are SGA have deficient use of intravenous triglycerides. After the intravenous administration of triglyceride emulsion, infants who are SGA have high free fatty acid and triglyceride levels, but ketone body formation is attenuated. This finding suggests that use and oxidation of free fatty acids and triglycerides are diminished in neonates who are SGA. Free fatty acid oxidation is important because it spares peripheral tissue use of glucose, whereas hepatic oxidation of free fatty acids may contribute the reducing (reduced nicotinamide adenine dinucleotide or reduced nicotinamide adenine dinucleotide phosphate) equivalents and energy required for hepatic gluconeogenesis. Deficient provision or oxidation of fatty acids may be partly responsible for the development of fasting hypoglycemia in these infants (Fig. 14-22).

Endocrine alterations have also been implicated in the pathogenesis of hypoglycemia in infants who are SGA. Hyperinsulinemia or excessive sensitivity to insulin may be only one factor in some infants who are SGA. Catecholamine

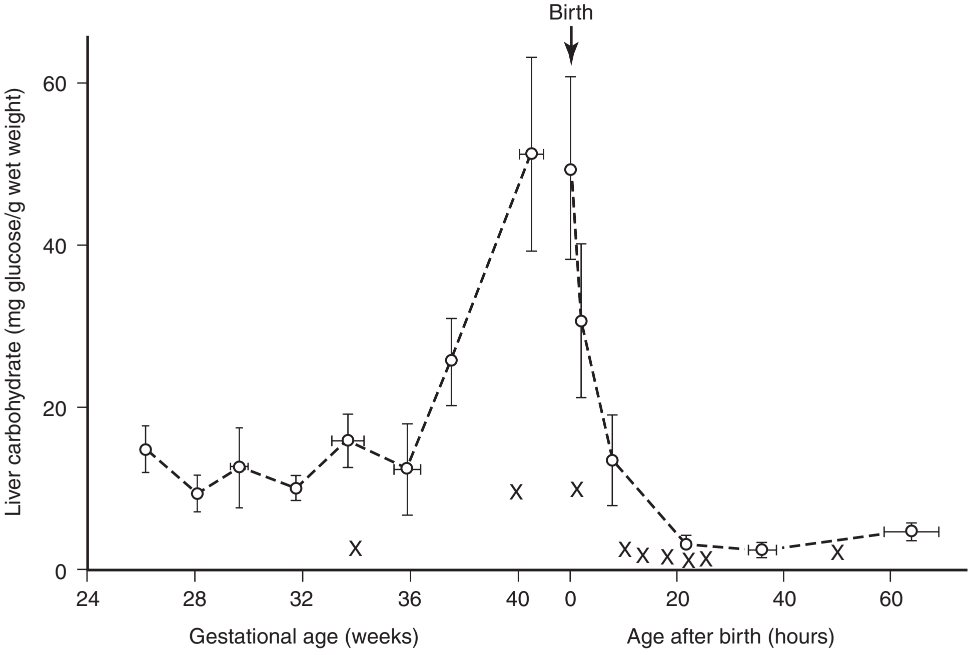

Figure 14–21. Fetal and neonatal hepatic glycogen content (X) in patients with intrauterine growth restriction. *(From Shelly H et al: Neonatal hypoglycemia,* Br Med Bull *22:34, 1966.)*

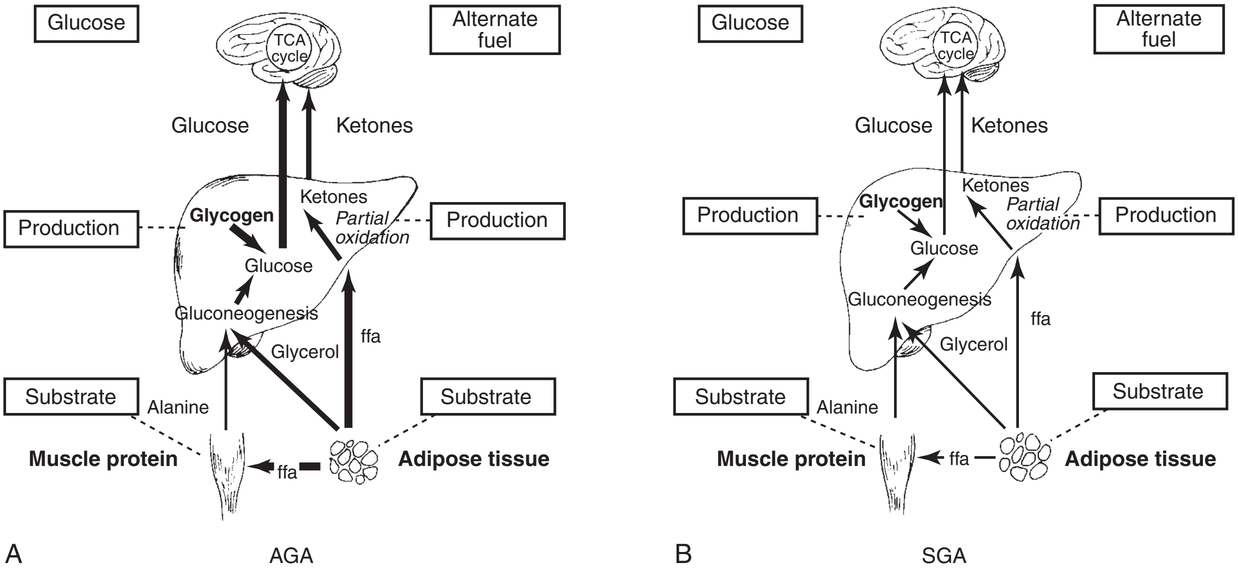

Figure 14–22. A and B, Postnatal glucose and fatty acid metabolic relationships in neonates who are appropriate for gestational age (AGA) (**A**) and small for gestational age (SGA) (**B**). *Arrows* reflect magnitude of flux. Infants who are SGA have diminished glycogen stores and gluconeogenesis. In addition, they may have attenuated fatty acid oxidation. ffa, free fatty acids; TCA, tricarboxylic acid. *(Modified from Adam PAJ: In Falkner F et al, editors:* Human growth *(vol 1), New York, Plenum Press, 1978.)*

release is deficient in these neonates during periods of hypoglycemia. Although basal glucagon levels may be elevated, exogenous administration of glucagon fails to enhance glycemia. These data suggest an abnormality of counter-regulatory hormonal mechanisms during periods of neonatal hypoglycemia in infants who are SGA.

With improved standards of care and attempts at early enteral feeding or intravenous alimentation, fasting hypoglycemia in a neonate who is SGA is a less common event. Before the start of alimentation, careful monitoring with Dextrostix reagent strips for determining blood glucose values identifies infants with asymptomatic hypoglycemia. If whole-blood glucose concentrations decline to less than 45 mg/dL during the first 3 days in term infants or preterm infants, and no untoward symptoms have occurred, enteral feedings or glucose infusion at 4 to 8 mg/kg per minute should begin. After this initial rate, the infusion should be titrated until blood glucose values achieve normal levels. If the hypoglycemia is symptomatic, particularly when seizure activity intervenes, an intravenous mini-bolus of 10% dextrose in water at 200 mg/kg should be given, followed by the infusion as just described. Infants who have been asphyxiated and infants who appear most undergrown according to the ponderal index are at greatest risk of having hypoglycemia (Fig. 14-23).

Temperature Regulation

After the birth of an infant whose gestation was complicated by uteroplacental insufficiency, the neonate's initial body temperature may be elevated (see also Chapter 30). When placental function fails, the neonate's heat-eliminating capacity also becomes deficient, resulting in fetal hyperthermia. On exposure to the cold environment of the delivery room, infants who are SGA can increase their heat production (oxygen consumption) appropriately because brown adipose tissue stores are not necessarily depleted as a result of IUGR. The infants' core temperature decreases, however, if the cold stress continues, implying that heat loss has exceeded heat production. Heat loss in these infants is partly caused by the large body surface area exposed to cold and the deficiency of an insulating layer of subcutaneous adipose tissue stores. Magnetic resonance imaging detection of reduced fetal fat stores is highly suggestive of IUGR that may result in fetal distress. Infants who are SGA have a narrower neutral thermal environment than term infants, but a broader one than premature neonates. In infants who are SGA, hypoglycemia or hypoxia or both interfere with heat production and may contribute to thermal instability. In all infants, particularly infants who are SGA, a neutral thermal environment should be sought to prevent excessive heat loss and to promote appropriate postnatal weight gain.

When nursed in a neutral thermal environment, infants who are SGA exhibit the usual decline of the respiratory quotient after birth, representing a shift toward free fatty acid oxidation. During the first 12 hours after birth, basal oxygen consumption may be diminished in neonates who are SGA. Similar observations have been recorded in utero among fetal lambs that are spontaneously SGA, suggesting in both situations that there is a deficiency of potentially oxidizable substrates. Supporting this hypothesis is the marked increase of oxygen consumption that occurs in well-alimented infants who are SGA. This latter observation is also analogous to the increase of energy production after the nutritional rehabilitation of infants with marasmic kwashiorkor.

The increase of oxygen consumption after fetal or infantile malnutrition represents the energy cost of growth. Infants who are SGA usually have a significantly smaller postnatal weight loss because they are maturationally capable of achieving an

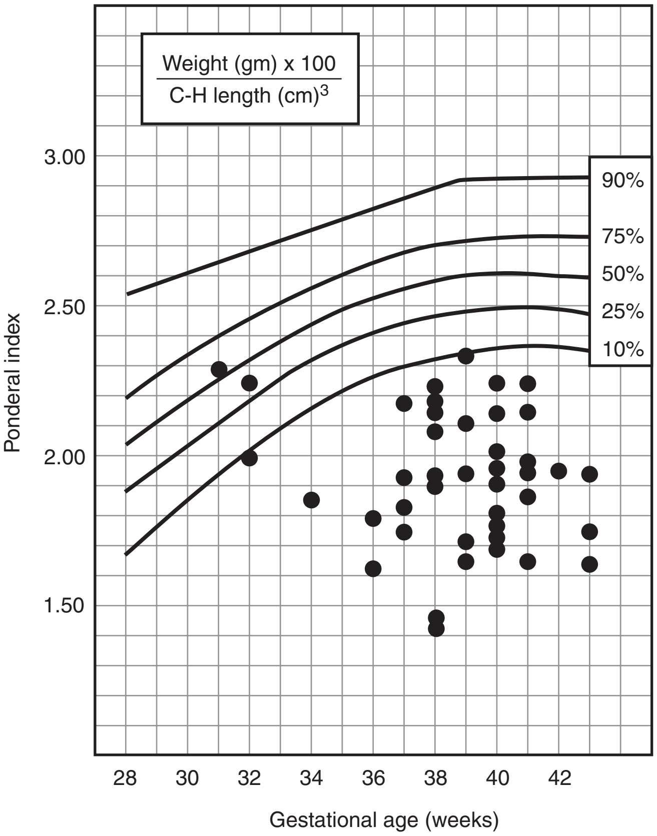

Figure 14–23. Relationship between ponderal index and neonatal hypoglycemia in intrauterine growth restriction. *Black circles* represent hypoglycemic infants. C-H length, crown-to-heel length. (*From Jarai I et al: Body size and neonatal hypoglycemia in intrauterine growth retardation,* Early Hum Dev *1:25, 1977.)*

adequate caloric intake earlier than premature neonates. Because of this enhanced caloric intake, infants who are SGA have a higher oxygen consumption than less mature neonates. Nutritional balance studies of premature infants who are SGA showed an increase of fecal fat and protein loss, despite faster rates of growth, compared with premature infants who are AGA. Energy storage was lower with IUGR, suggesting less fat deposition.

A subgroup of neonates who are SGA do not show an elevation of oxygen consumption after appropriate caloric intake. These infants have had low-profile intrauterine growth and may be considered to have had "primordial" fetal growth restriction. Their growth is set and fixed at a slower rate, and their eventual growth potential is reduced. The diminished body cell number in congenitally infected infants and in infants with chromosomal disorders exemplifies primordial growth restriction in these neonates.

Hyperviscosity-Polycythemia Syndrome

The plasma volume immediately after birth of infants who are SGA averages 52 mL/kg compared with 43 mL/kg in infants who are AGA. When equilibrated at 12 hours of life, the plasma volume becomes equivalent in the two groups. In addition to an enhanced plasma space, the circulating red blood cell mass is expanded. Fetal hypoxia and subsequent erythropoietin synthesis induce excessive red blood cell production. Alternatively, a placental-fetal transfusion during labor or periods of fetal asphyxia may result in a shift of placental blood to the fetus. Nonetheless, the elevation of the hematocrit level potentially increases blood viscosity, which interferes with vital tissue perfusion.

The altered viscosity adversely affects neonatal hemodynamics and results in an abnormal cardiopulmonary and metabolic postnatal adaptation, producing hypoxia and hypoglycemia. Polycythemic infants are at increased risk of developing necrotizing enterocolitis. In the event that polycythemia is present (central hematocrit level greater than 65%) with symptoms, appropriate therapy is directed at correcting hypoxia and hypoglycemia, and a partial exchange transfusion to reduce blood viscosity and to improve tissue perfusion should be considered. (See also Chapter 46.)

Other Problems

IUGR is associated with a slower than normal production of long-chain polyunsaturated fatty acids. Intestinal absorption of xylose is also attenuated. At birth, cord prealbumin and bone mineral content are low in term infants who are SGA. Thrombocytopenia, neutropenia, prolonged thrombin and partial thromboplastin times, and elevated fibrin degradation products may also be problems in infants who are SGA. Sudden infant death syndrome may be more common in infants with IUGR. Inguinal hernias also typically occur in preterm infants with IUGR. Additional problems and their management are noted in Table 14-7.

Follow-up

When infants who are SGA and have serious congenital malformations or viral infections are excluded, the remaining neonates should benefit from optimal antenatal detection, very careful management of pregnancy, and avoidance of hypoxic fetal distress. In addition, with ideal neonatal intensive care, the morbidity and mortality rates for infants who are SGA should be reduced to a minimum, and postnatal developmental handicaps should be diminished. Nonetheless, these infants continue to contribute to the excessive fetal and neonatal morbidity and mortality rates. The neonatal mortality rate is much greater than that for term neonates and for weight-matched premature neonates. The incidence of fetal death remains higher for infants who are SGA.

In addition to the etiologic events that lead to the development of IUGR, these infants have additional multisystem problems that compromise survival and future growth or development further. Among these fetuses, the perinatal mortality rate is 10 times that of fetuses who are AGA. The incidence of intrauterine fetal death is greatest among the most severely undergrown infants. Antepartum and intrapartum events contribute to fetal death. Lethal congenital malformations and birth asphyxia are the two leading causes of death among neonates who are SGA. Infants with very low birthweight who are SGA (less than 1500 g) are at significant risk of reduced postnatal growth and development in addition to chronic neonatal sequelae, such as bronchopulmonary dysplasia or retinopathy of prematurity.

Developmental Outcome

When infants with congenital infections and severe malformations are excluded, a heterogeneous group of neonates with IUGR remains. Intellectual and neurologic functions in these remaining infants depend heavily on the presence or absence of adverse perinatal events, in addition to the specific cause of IUGR. Cerebral morbidity is worsened by hypoxic-ischemic encephalopathy subsequent to birth asphyxia, and by the postnatal problems of hypoxia and hypoglycemia. The prognosis must consider all the potentially adverse perinatal circumstances in addition to IUGR. When these perinatal problems are minimal or are avoided, a neonate who is SGA may still have cerebral developmental problems, especially in the presence of relative head growth restriction, prematurity (birthweight less than 1500 g), or poor postnatal catch-up growth.[9] If term neonates who are AGA are used as a standard, term infants who are SGA exhibit developmental problems when they are examined at follow-up at ages 2 and 5 years and into adult years. Follow-up of these infants usually reveals little difference in intelligence quotient or neurologic sequelae; however, their school performance is poor, partly because of behavioral, visuospatial, visuomotor, and learning disorders.

Preterm infants who are SGA may have an even greater percentage of abnormal neurodevelopmental outcomes than term neonates who are SGA. Infants who were SGA early in gestation, showing decreased growth of the biparietal diameter before 26 weeks' gestation, and infants with symmetric growth restriction have diminished developmental quotients in infancy. Infants who are SGA with poor postnatal catch-up growth are at risk for lower IQs and psychological problems (conduct disorders, emotional issues). Reading and math scores are diminished, and executive cognitive functions are reduced, especially in infants who showed abnormalities of fetal aortic or umbilical artery blood flow.[42,43,68,69,72]

Some follow-up observations in term and preterm neonates who are SGA are favorable: These neonates compare well with their counterparts who are AGA. Cerebral palsy is uncommon after uncomplicated IUGR. Infants who are SGA are a heterogeneous group, and the populations investigated may vary in the severity of neurodevelopmental handicap; similarly, antenatal detection and perinatal management vary among high-risk centers. These latter favorable reports may represent the outcome after optimal obstetric management and neonatal care. Adults who were SGA report that they are well adjusted, have good health-related quality of life, and are socially satisfied with their lives.[66]

Another major determining influence on neonatal neurodevelopmental outcome in infants who are SGA is the family's socioeconomic status. Parent educational background, place of rearing, and environmental conditions all have a strong effect on outcome. Infants who are SGA born to families of higher socioeconomic status showed little developmental difference on follow-up, whereas infants born to poorer families had significant developmental handicaps (see also Chapter 41). In addition, neurodevelopmental outcome is favorably influenced by breast feeding.

Growth

Postnatal growth after IUGR depends partly on the cause of the growth restriction, postnatal nutritional intake, and social environment. Although birthweight correlates best to maternal weight, postnatal growth is related to maternal and paternal growth characteristics in normal infants. Neonates who are SGA who have primordial growth restriction related to congenital viral, chromosomal, or congenital malformation syndromes, or undefined etiologies remain small throughout life. Infants whose intrauterine growth was inhibited late in gestation because of uterine constraint, placental insufficiency, or nutritional deficits have catch-up growth after birth and approach their inherited growth potential when provided with an optimal environment. Infants with a low ponderal index or asymmetric growth restriction have an accelerated growth phase after adequate postnatal caloric intake has been established, which suggests release of an in utero constraining factor after birth. Catch-up growth occurs in about 90% of SGA infants; it occurs usually by 2 years of age and is most likely to occur in infants who have normal birth length despite being SGA. Preterm infants with severe IUGR are at higher risk of short stature. In addition, despite the catch-up period, some infants who had IUGR remain smaller than appropriately grown neonates (Fig. 14-24), especially infants who had the onset of growth restriction before 26 weeks.

Catch-up growth usually results in increased abdominal adipose tissue with less than normal development of lean body mass and has been associated with adult morbidities such as obesity and type II diabetes. Excessive catch-up growth and some adult morbidities may be attenuated if the neonate is fed human milk.

Adolescents who had IUGR and have exhibited catch-up growth may develop reproductive endocrine abnormalities.[14,70] Anovulation has been reported in nonobese and obese women after being IUGR and may be due to hyperinsulinemic hyperandrogenism. This problem may respond to metformin therapy.

Adolescent boys may exhibit testicular dysfunction after having IUGR. This dysfunction is manifest by decreased testicular size, low testosterone levels, and elevated luteinizing hormone levels.[13] Testicular dysfunction is more often noted in men without catch-up growth in height.

Growth hormone therapy for IUGR has produced growth acceleration.[17,19,22] Some infants with IUGR show abnormal postnatal growth hormone physiology, suggesting growth hormone resistance at the receptor or IGF signal transduction pathways. Growth hormone therapy is indicated in children who were SGA and who remain short and do not show catch-up growth by 2 years of age (United States) or 4 years of age (Europe). Growth hormone therapy enhances linear growth and improves self-perception. Glucose tolerance has not been affected, but insulin sensitivity may be reduced in children treated with growth hormone.

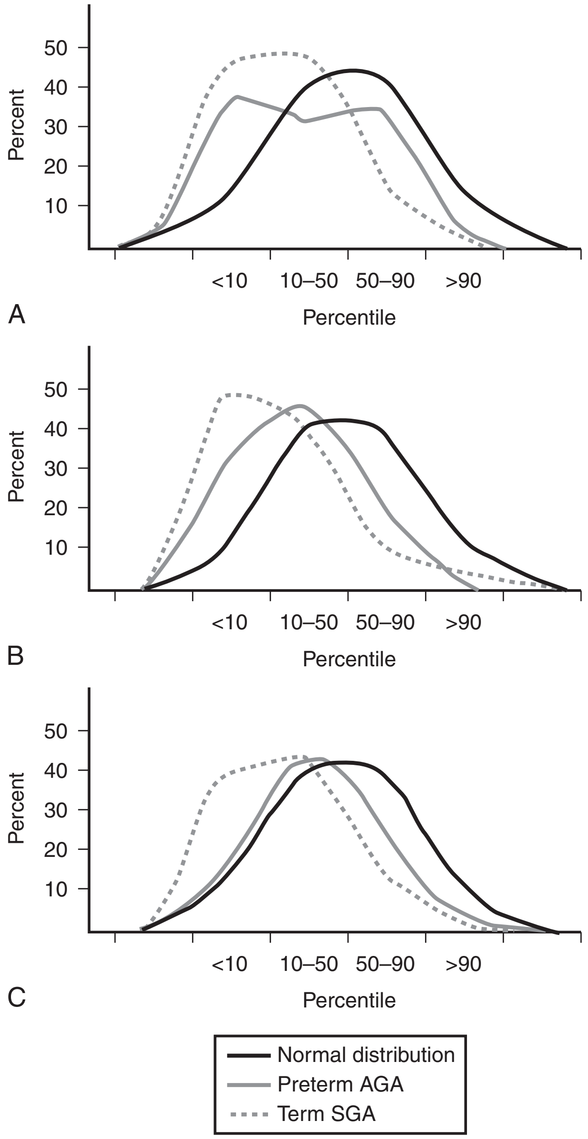

Figure 14–24. Eventual physical growth of neonates who were small for gestational age (SGA), born full-term; appropriate for gestational age (AGA), born premature; and AGA, born full-term, at 4 years of age. **A**, Height. **B**, Weight. **C**, Head circumference. *(From Lubchenco L:* The high-risk infant, *Philadelphia, 1976, Saunders.)*

CHAPTER 15

Hypertensive Disorders of Pregnancy

Dinesh M. Shah

Hypertensive disorders of pregnancy are one of the most serious complications in pregnancy because they cause serious maternal and perinatal morbidity and mortality. Although numerous hypertensive patients have relatively good outcome, difficulty in differentiating among various hypertensive conditions, inability to predict which patients are at highest risk, and variability in the progression of preeclampsia make these disorders the greatest challenge of clinical medicine in obstetrics.

CLASSIFICATION

Various systems have been used to classify hypertensive disorders of pregnancy. Some terms, such as *pregnancy-induced hypertension,* have misleading connotations about the underlying mechanism. Misleading terms reflect the lack of clear understanding about the etiology and lack of a gold standard diagnostic test. The current classification was developed by the National Institutes of Health working group on hypertension in pregnancy.[49] This classification proposes that hypertensive disorders of pregnancy be divided into four categories: preeclampsia-eclampsia, gestational hypertension, chronic hypertension, and preeclampsia superimposed on chronic hypertension.

Preeclampsia-Eclampsia

Preeclampsia is new-onset hypertension with proteinuria with or without edema. Edema alone with hypertension is unreliable for diagnosis of preeclampsia because significant edema occurs in normal pregnancy, and it is difficult to distinguish physiologic change from pathologic edema. Edema that occurs in nondependent sites, rapidly increasing edema (as evidenced by rapid weight gain of at least 2.25 kg or 5 lb per week), or persisting facial edema after the patient has been upright for several hours should be suspected as pathologic edema. Hypertension is defined as blood pressure greater than 140/90 mm Hg or mean arterial pressure greater than 105 mm Hg. Proteinuria is defined as protein excretion of 30 mg/dL in a random specimen (equal to 1+ on urine strips) or 300 mg in a 24-hour urine specimen. Eclampsia is the development of convulsions or coma or both in the clinical setting of preeclampsia.

Gestational Hypertension

Gestational hypertension is hypertension occurring after the 20th week of pregnancy or during the first 24 hours postpartum without evidence of proteinuria or other signs of preeclampsia and in the absence of evidence of preexisting hypertension.

Chronic Hypertension

Chronic hypertension is hypertension diagnosed before pregnancy or before the 20th week of pregnancy. Hypertension is defined as blood pressure greater than 140/90 mm Hg. This definition may overlook isolated systolic or diastolic hypertension. Some investigators have suggested use of mean arterial pressure greater than 105 mm Hg as the alternative diagnostic criterion. Mean arterial pressure is calculated as diastolic pressure plus one-third pulse pressure (pulse pressure is systolic pressure minus diastolic pressure). Hypertension diagnosed any time during pregnancy but persisting beyond the 42nd postpartum day is also classified as chronic hypertension.

Superimposed Preeclampsia

Superimposed preeclampsia is either aggravation of hypertension or onset or increase in degree of proteinuria in a patient with a chronic hypertensive disorder. Aggravation of hypertension is an increase in systolic pressure by 30 mm Hg or diastolic pressure by 15 mm Hg.

Comment on Classification

Increases of 30 mm Hg in systolic blood pressure and of 15 mm Hg in diastolic blood pressure have been shown to be unreliable criteria for diagnosis of preeclampsia. Most patients with an increase of this magnitude do not have a hypertensive disorder.[94] One of the difficulties of diagnosing hypertension before the 20th week of gestation is that a patient's blood pressure is generally lower in the first half of pregnancy compared with the nonpregnant state. The lowering of blood pressure is a result of the vasorelaxant effect of gestation, which masks hypertension in some patients before the 20th week of pregnancy. Patients with chronic hypertension have been shown to have a greater decline in their blood pressure than normal patients.[77] Diagnosis of chronic hypertension as persisting after the 42nd postpartum day is useful only for classifying patients retrospectively (e.g., for grouping patients in a study), but is not useful for clinicians in managing the index pregnancy.

PREECLAMPSIA-ECLAMPSIA

Pathophysiology

Uteroplacental ischemia is a fundamental abnormality recognized in preeclampsia-eclampsia.[53] The diagnosis of uteroplacental ischemia is based on histopathologic examination of the placenta, revealing ischemic lesions[4]; study of the uterine vascular bed, revealing vascular lesions known as acute atherosis[101]; restriction of fetal growth secondary to reduced uteroplacental blood flow[38]; and radionuclide studies of uteroplacental perfusion, showing reduced clearance of radionuclide.[44] Understanding the pathogenic mechanism requires understanding uterine vascular modeling in implantation and development of the placenta and understanding the mechanisms of regulation of blood flow in the maternal uteroplacental vasculature.

UTERINE VASCULAR MODELING

Terminal uterine vessels are known as spiral arteries. In the process of gestational development, under the influence of sex steroids, these vessels grow in length and to some degree in diameter.[26] Trophoblastic invasion of these vessels occurs in the process of implantation and development of the placenta. Trophoblastic invasion results in complete replacement of endothelium by a layer of trophoblastic cells. The medial coat of the vessel, which consists of smooth muscle cells and connective tissue, is completely replaced by the invading trophoblasts.[57] At the end of this remodeling, the spiral artery is made of a thin adventitial layer internally lined by trophoblasts; it is considerably dilated in diameter and is known as the uteroplacental vessel.[11]

It has been suggested that trophoblastic invasion occurs in two phases. The first phase extends from the time of implantation until the 10th to 12th week of gestation[57]; invasive growth progresses to two-thirds depth in the decidua. The second phase extends from the 12th week to the 16th to 18th week of gestation. The vessels are remodeled up to the terminal resistance portion of the vessel into the myometrial layer; this results in a marked decrease in the resistance to the blood flow into the uteroplacental vessels and into the intervillous space. As placentation progresses, trophoblastic invasion incorporates greater numbers of vessels, until an average of 100 decidual arteries are tapped for intervillous circulation.[11]

In patients who eventually develop preeclampsia, the invasion depth in the second-phase trophoblastic invasion might be deficient.[56] The insufficient depth allows greater numbers of decidual spiral arteries to retain the resistance portion of the vessel, which prevents adequate dilation of these vessels. More important, the contractile portion of these vessels remains intact, which has profound implications for the effect of vasomotor regulators of circulation.

VASOMOTOR REGULATION OF UTEROPLACENTAL CIRCULATION

Regulation of Uterine Blood Flow

It is now well recognized that many organs have mechanisms for regional regulation of blood flow. The uterus is similar to the kidney in its embryologic origin, anatomic vascular arrangement, and mechanisms for regulation of blood flow. Similar to the kidney, uteroplacental circulation produces various vasodilators and vasoconstrictors, including eicosanoids,[92] endothelin,[33] nitric oxide,[42] renin,[45,73,89] and angiotensinogen.[46,73]

Various aberrations occur in these vasomotor regulators in preeclampsia. Prostaglandin production has been shown to be decreased in preeclampsia; however, such deficiency accounts for only a small degree of change in blood pressure (3 to 5 mm Hg).[21] Thromboxane is considered a counterregulatory vasoconstrictor eicosanoid to prostacyclin, and its production has been shown to be increased.[20] Viewing these two facts together, the balance of eicosanoids could be disturbed in preeclampsia.[21,97] Some investigators have suggested that endothelin levels may be increased in preeclampsia.[91] Others have shown that it is not.[72]

In experimental gravid animal models, pharmacologic interventions to decrease nitric oxide production are associated with development of systemic hypertension.[103] Nitric oxide production by measurements of urinary metabolite has been shown not to be deficient in human preeclampsia, however.[16]

Role of the Renin-Angiotensin System

The renin-angiotensin system might be involved in the pathogenesis of preeclampsia.[87] The role of angiotensin II in regulating uterine blood flow directly or through alterations of eicosanoids has been suggested in experimental settings. Uterine venous angiotensin II levels are higher in hypertensive human pregnancy.[59] More important, systemic vasculature becomes more responsive to angiotensin II in preeclampsia.[23]

In view of evidence for uteroplacental ischemia and evidence for local renin and angiotensinogen production in the uterus, it is reasonable to assume that uterine vasculature is also modified to become more sensitive to angiotensin II in human preeclampsia. This vascular maladaptation, i.e., increased responsiveness to angiotensin II and development of hypertension, was first described by Goldblatt similar pathophysiology has been shown in renin gene overexpression models with development of hypertension.[47] This research on renin gene overexpression models with hypertension emphasizes the role of renin in the evolution of vascular maladaptation.

The change in the vasculature in renin-mediated hypertension is primarily driven by functional changes in the vasculature. Such functional changes in vasculature in renin-mediated hypertension are biochemically mediated by alterations in the cyclooxygenase pathway of arachidonic acid metabolism and increased thromboxane production,[100] protein kinase C-mediated mechanism and its effect on calcium handling by the vascular smooth muscle,[50] alterations in the Na^+-K^+ pump and cotransport,[51] and change in endothelin expression and release.[7] Initial change in vasculature in renin-mediated vasoconstriction seems to be mediated through increased sympathoadrenal activity. Many of these alterations have been described in human preeclampsia,[20,21] including increased sympathoadrenal activity.[70]

Takimoto and colleagues[90] reported the development of preeclampsia-eclampsia syndrome by crossbreeding transgenic mice, with the introduction of human renin (*Ren*) and human angiotensinogen (*AGT*) genes into the mouse genome. Specifically, when male mice carrying human *Ren* were mated with female mice carrying human *AGT,* preeclampsia syndrome developed, and renin overexpression was shown on the fetal side of the placenta. One important aspect of the mouse model of preeclampsia is that fetal renin from the placenta seemed to transfer to the maternal circulation much more readily than is reported in humans.[36]

In human preeclampsia, renin gene expression is increased in the decidua vera on the maternal side.[75] Increased renin production from the uterus has been shown to occur in response to decreased blood flow to the uterus in experimental settings.[102] Collectively, these data suggest a role of increased renin production in the uteroplacental interphase in the pathogenic mechanism of preeclampsia.

Increased heterodimerization of angiotensin AT_1 and bradykinin B_2 receptors has been described in preeclampsia.[1a] These investigators have suggested the concept that AT_1-B_2 heterodimerization mediates at least part of the increased responsiveness to angiotensin II in preeclampsia by using the B_2 intracellular domain for the signal transduction.[1a] Susceptibility of AT_1 homodimers to inactivation by peroxide treatment suggests that oxidative stress of normal pregnancy may confer some of the angiotensin II refractoriness.[1a] The mechanism by which the AT_1-B_2 heterodimerization is induced is not yet defined.

Patients with preeclampsia develop autoantibodies against the second loop of the AT_1 receptor (AT_1-AA),[96] which might be another mechanism involved in AT_1 receptor and adrenoreceptor signaling. How an antibody against the AT_1 receptor could cause signal transduction to occur through the α_1 adrenoreceptor remains unexplained. These antibodies enhance the tissue factor expression in vitro with increased immunoreactivity for tissue factor in preeclamptic placentas.[10] These data on AT_1-AA correlate with the findings of anti-ssDNA and anti-dsDNA autoantibodies in preeclampsia,[104] suggesting an abnormal or unrestrained B cell activation in preeclampsia or perhaps aberrantly increased antigen presentation, or both.

Angiotensinogen mutation with increased angiotensin II production and susceptibility to development of preeclampsia has been shown in some populations, but not in others.[98] Because other biochemical aberrations that mediate vascular maladaptation are renin mediated, renin from uteroplacental interphase might have a role in initiating the pathogenesis of preeclampsia (Fig. 15-1).

In addition to development of systemic hypertension, alterations in regional organ circulation occur in sites that are normally renin-angiotensin dependent. This reduction in local blood flow could explain the spectrum of clinical manifestations of preeclampsia.

Vasomotor Implications of Vascular Modeling

The intactness of the resistance portion of the uteroplacental vessels with preserved ability for vasoconstriction should have profound implications for uteroplacental ischemia. These vessels should also become increasingly responsive to angiotensin II that is produced locally. The local renin-angiotensin system could initiate vasoconstriction-mediated ischemia and cellular injury in the uteroplacental vascular bed.

PATHOPHYSIOLOGIC BASIS OF CLINICAL MANIFESTATIONS

The renin-angiotensin system is involved in physiologic regulation of blood flow in various organs, including the heart and systemic vasculature and the uterus, kidney, liver, and brain (Table 15-1). These are also the sites for major clinical manifestations of preeclampsia-eclampsia, which emphasizes the role of the renin-angiotensin system in the pathogenesis of this disorder. Clinical manifestations are described here according to the systemic or regional circulations involved. The primary mechanism at all sites is increased responsiveness to angiotensin II, leading to increased vascular resistance initially and vasoconstriction later with attendant hypoxemia and cell damage. When vasoconstriction and hypoxemia occur, endothelial dysfunction sets in, and free radical formation and lipid peroxidation may accelerate the process further.[68] Endothelial dysfunction can occur earlier in individuals susceptible to such endothelial damage (e.g., thrombophilic conditions).[34] Other studies suggest that such individuals might not be at an increased risk.[52]

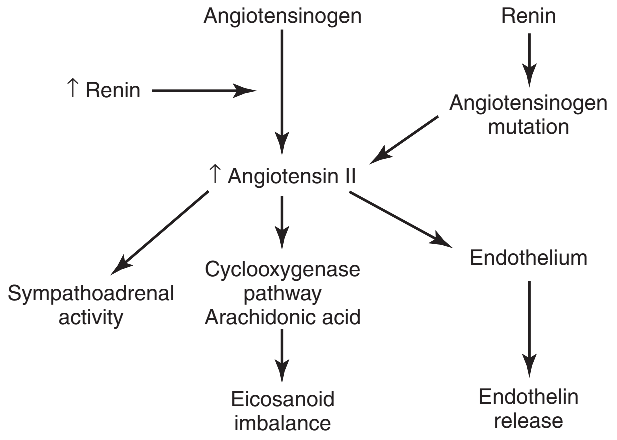

Figure 15–1. Renin-angiotensin system in pathogenesis of preeclampsia.

TABLE 15–1 Findings and Clinical Manifestations of Preeclampsia

Vasculature or System	Findings	Clinical Manifestations
Cardiovascular	Increased cardiac output and systemic vasoconstriction	Systemic hypertension
	Increased hydrostatic pressure	Generalized edema
	High cardiac output and hypertension	Intravascular hemolysis
Uteroplacental	Uteroplacental insufficiency	Fetal somatic growth deficiency; fetal hypoxemia and distress
	Decidual ischemia	Abruptio placentae; placental infarcts
	Decidual thrombosis	Thrombocytopenia
Renal	Decreased renal blood flow and glomerular filtration rate; endothelial damage	Proteinuria; elevated creatinine and decreased creatinine clearance; oliguria
	High AII responsiveness of tubular vasculature	Elevated uric acid
	All of the above	Renal tubular necrosis and renal failure
Cerebrovascular	Cerebral motor ischemia	Generalized grand mal seizures (eclampsia)
	High cerebral perfusion pressure with regional ischemia	Cerebral hemorrhage
	Cerebral edema	Coma
	Regional ischemia	Central blindness; loss of speech
Hepatic	Ischemia; hepatic cellular injury	Elevated liver enzymes
	Mitochondrial injury	Intracellular fatty deposit
Hematologic	Intravascular hemolysis	Schistocyte burr cells; elevated free hemoglobin and iron; decreased haptoglobin levels
	Decidual thrombosis, release of FDP	Thrombocytopenia; antiplatelet antibodies

AII, angiotensin II; FDP, fibrin degradation products.

Cardiovascular Manifestations

Increased sympathoadrenal activity may mediate increases in cardiac output. Increase in cardiac work demanded by increased cardiac output is generally well tolerated by young patients, but it may occasionally precipitate left ventricular failure. Decreased renal perfusion, high hydrostatic pressure owing to the cardiovascular changes, and decrease in oncotic pressure owing to proteinuria compounded by fluid overload may result in development of pulmonary edema.

Systemic vasculature is most frequently and fairly consistently involved with vasoconstriction, the primary manifestation being development of hypertension. Usually, systolic and diastolic blood pressures are elevated, and hypertension is proportional to renal manifestations, especially proteinuria, at least in uncomplicated cases. Hypertension to some degree depends on increased sympathoadrenal activity, which explains the fluctuations in blood pressure and accelerations related to anxiety.

High cardiac output in the face of markedly increased peripheral vascular resistance may result in traumatic intravascular hemolysis. This condition can cause a decreased haptoglobin level, increased free hemoglobin level, increased bilirubin levels, burr cells and schistocytes in the peripheral blood, and an increased free serum iron level.

Uterine Vasculature

Initially, high cardiac output and increased vascular resistance without change in vessel diameter may result in increased uteroplacental perfusion. Later, with a marked increase in local vasoconstriction, regional blood flow would decrease.

Uteroplacental ischemia and placental infarcts are well-recognized pathologic findings of preeclampsia-eclampsia syndrome.[53] Decreased uteroplacental blood flow explains increased frequency of somatic growth deficiency in this condition[38] (see also Chapter 14). Severe reductions in uteroplacental blood flow can cause fetal hypoxemia, which is clinically manifested as fetal distress, hypoxemic multiorgan failure, or death. Uteroplacental interface hypoxemia can also result in cellular injury to the decidua and injury to the vascular wall itself, with resultant small hemorrhages.

Two processes—hypoxemic cell injury and hemorrhage—sometimes cause small disruptions of placental attachment, which cause further disruption of the vascular wall as a result of the mechanics of physical separation. Disruption of the vascular wall causes bleeding in the uteroplacental interface; this may explain development of abruptio placentae.

Uteroplacental interface vessels normally have fibrin deposition, a process that can be aggravated by vasoconstriction, and further decreases in the blood flow in these vessels. These reductions in blood flow explain the decidual thrombosis and initiation of thrombocytopenia with local platelet consumption.[64] Dissemination of small fibrin degradation products from these vessels and release of tissue thromboplastin from decidual and trophoblast cell injury can cause disseminated intravascular coagulopathy.[60]

Renal Vasculature

Decreased renal blood flow and high renal perfusion pressure and associated hypoxemia can cause glomerular injury, which causes proteinuria. Glomerular injury may be associated with fibrin deposits in the basal layer and swelling of endothelial cells, resulting in glomerular endotheliosis seen in renal histology.[19] A severe decrease in renal blood flow can cause oliguria, and severe vasoconstriction and hypoxemia with cellular injury might explain renal tubular necrosis seen occasionally in preeclampsia.

Excess circulating placental soluble fms-like tyrosine kinase 1 (sFlt-1), an antagonist of vascular endothelial growth factor (VEGF) and placental growth factor, has been shown in preeclampsia. By reducing the circulating levels of VEGF and placental growth factor, sFlt-1 may contribute to the endothelial dysfunction and impaired renal vasorelaxation.[32,43] This sFlt-1 is a splice variant of VEGF receptor-1 (VEGFR-1); it is produced by the placenta and has been known to enter the maternal circulation. Administration of sFlt-1 to pregnant rats induced hypertension, proteinuria, and glomerular endotheliosis.[43] Recent experimental evidence showing attenuation of hypertension and decrease in renal injury by infusion of recombinant VEGF 121 in a rat model further validates the role of sFLT-1 in the pathogenesis of preeclampsia.[37a] Similarly, soluble endoglin, a novel placenta-derived soluble transforming growth factor-β coreceptor, seems to contribute to the pathophysiology by dysregulating signaling in the vasculature.[93]

Decreased renal tubular blood flow (this vasculature is sensitive to angiotensin II) results in proximal tubular exchange of urate in favor of plasma, which explains frequent association of elevated serum uric acid as a manifestation of preeclampsia. Elevated uric acid more accurately reflects angiotensin II responsiveness,[18] explaining the ability of elevated uric acid to predict fetal death better than systemic hypertension does.[66] Decreased glomerular filtration rate, combined with proteinuria-induced decrease in oncotic pressure and high hydrostatic pressure secondary to increased cardiac output, increased vascular resistance, and sodium and obligatory water retention (aldosterone effect), causes increased dependent and even generalized edema of preeclampsia.

Rare cases of diabetes insipidus of renal origin occur. Measurements of arginine vasopressin levels are generally normal, and placental aminopeptidase is responsible for rapid degradation of arginine vasopressin, resulting in functional deficit.

Hepatic Vascular Changes

Angiotensin II responsiveness of hepatic vasculature is well recognized; it has been used for selective chemotherapy for tumors by angiotensin II infusion-induced vasoconstriction of normal vasculature to protect normal liver tissue. In later phases of disease, hepatic vasoconstriction-mediated hypoxemia and cellular injury are expected to result in release of hepatic enzymes into the circulation, with elevation of liver enzymes in blood.[31] Hepatic vasculature in the subcapsular region seems particularly susceptible to injury, resulting in small hemorrhages. In combination with disseminated intravascular coagulopathy, these hemorrhages can become larger and cause major subcapsular hematomas of the liver. Tissue injury with edema of liver parenchyma and capsule and with stretching of the capsule could explain the hepatic origin of epigastric pain.

HELLP syndrome[99] is a combination of intravascular hemolysis, elevated liver enzymes, and thrombocytopenia or low platelets. Acute fatty liver of pregnancy (AFLP)[30,45] is a condition with a predominantly hepatic manifestation; it is frequently associated with thrombocytopenia and frequently occurs without cardiovascular manifestations of preeclampsia. Cellular hypoxemic injury explains mitochondrial damage, disruption of fatty acid metabolism, and deposition of microvesicular fat in hepatic cells. Susceptible women (women with a carrier state of deficiency of enzymes of fatty acid metabolism and short-chain and long-chain fatty acid dehydrogenase) might develop AFLP.[28] In most cases, AFLP occurs independent of preeclampsia. There seems to be some overlap in the pathophysiology of AFLP and preeclampsia with AFLP; hepatic manifestations predominate in individuals with such susceptibility. Mitochondrial enzyme defects may occur as gene defects or be acquired through cell injury mediated by free radicals.

Central Nervous System

High cardiac output and increased vascular resistance may be associated with greater regional circulation in the brain at higher perfusion pressure.[2] Some regions of the brain, especially in advanced stages of the disease, might have locally decreased perfusion.

Vasoconstriction and hypoxemia in the microvasculature of the brain result in cellular injury. The injury causes extracellular release of intracellular sodium, which provides the means for generating aberrant electric impulses. The motor cortex seems to be particularly susceptible to such cellular injury, with resultant convulsions and eclampsia.[61] Vasoconstriction of different regions of the brain produces different manifestations: Vasoconstriction in the frontal cortex causes frontal headache, constriction in the occipital cortex causes visual disturbances and central blindness, and constriction in the Broca area causes loss of speech. Blindness may also develop as a result of retinal detachment. Most patients who develop blindness recover completely without medical intervention. In cases of cerebral edema, coma and loss of recent memory of specific convulsive episodes occur.

Cerebrovascular accidents occur as a result of cerebral vasospasm, hypoxemia-induced vascular damage, and systolic hypertension that causes mechanical rupture or disruption of the vessel wall. Current data in developed countries suggest that almost 70% of hypertension-related maternal mortality is due to cerebrovascular accidents.[63] Data on stroke and severe preeclampsia and eclampsia suggest a paradigm shift to focus on reduction in systolic blood pressure.[41]

Hyperreflexia has been recognized as a sign of neurologic irritability in epilepsy and is seen before eclamptic seizures, but many women have normally active deep tendon reflexes without neurologic irritability.

Clinical Considerations

PREDISPOSING FACTORS

Several factors are associated with, or suggested to be associated with, an increased risk of preeclampsia-eclampsia, as follows:

Parity: Eclampsia and preeclampsia are recognized to occur more frequently in the first pregnancy.[6]

Age: Relationship to age is described as a J-shaped curve with slightly increased incidence in young primigravidae and a more pronounced increased incidence in older primigravidae.[6]

Race: Incidence of hypertension is not increased in African Americans, in contrast to a commonly held belief, although a higher incidence of proteinuria is observed.[80]

Family: In a study of women with eclampsia, their daughters had an incidence of preeclampsia of 26%, their sisters had an incidence of 37%, and their daughters-in-law had an incidence of 8%.

Genetics: Genetic predisposition has been suspected on the basis of increased familial incidence, suggesting a recessive trait possibly of maternal origin.

Diet: Most studies suggest that protein, carbohydrate, or total calorie intake does not influence the incidence of preeclampsia.

Social status: Several reports suggest that populations with lower socioeconomic status have a higher incidence of preeclampsia and severe preeclampsia.

Twin pregnancies: Twinning is associated with a higher incidence of preeclampsia compared with singleton gestation. Severe preeclampsia occurs more frequently in monozygotic twinning, especially in multiparous women.

Diabetes: The incidence of preeclampsia is generally thought to be increased in diabetic pregnancies.[12]

Hydatidiform mole: The higher incidence and early onset of preeclampsia are well recognized in molar gestation[54]; these features are also observed in triploidy gestations, which usually have partial mole.[84]

Hydrops fetalis: The incidence of preeclampsia seems to be increased only in nonimmune hydrops fetalis.[71]

Polyhydramnios: Increased incidence of preeclampsia observed in association with polyhydramnios is related to causes of polyhydramnios, including multiple gestation, diabetes, and hydrops fetalis.[71]

Climate and season: Despite considerable interest and analysis, climatic and seasonal factors do not seem to contribute to the incidence of preeclampsia.

Cigarette smoking: The incidence of preeclampsia is lower in smokers compared with nonsmokers.[85] If preeclampsia does occur, however, fetal risks are greater in smokers compared with nonsmokers.

Although susceptibility to preeclampsia might be increased by maternal thrombophilic mutations, most of the data have been inconclusive and contradictory. A more recent case-control study suggests, however, that prevalence of factor V and factor II mutations is increased in patients with preeclampsia without a previous thromboembolic disorder.[3] Researchers have suggested that the thrombophilic mechanism might interact with other pathogenic factors to determine clinical features of the disease.[3]

DIFFERENTIAL DIAGNOSIS

One of the most fundamental issues faced by clinicians is differentiation of a preexisting hypertensive disorder from the development of preeclampsia. Preeclampsia is a progressive disorder of increasing severity, which demands intervention in the form of delivery to halt the progression of the condition. This contrasts with preexisting hypertensive disorders, which exhibit stable manifestations, allowing clinicians to prolong gestation.

This difference in clinical course of action has profound implications for prevention of interventional prematurity. Because preeclampsia is progressive, observation of the patient may reveal progression of the disorder. This approach is fraught, however, with the risk of the patient’s developing serious complications of preeclampsia. Such an approach is valid when the severity of suspected preeclampsia is judged to be mild or moderate, and gestational age is preterm enough to justify postponement of delivery. This philosophy should maximize perinatal outcome within the bounds of maternal safety.[76]

Preexisting essential hypertension should be suspected in the absence of proteinuria and other laboratory findings, especially if there is a family history of hypertension, and in the presence of maternal obesity. Corroborative information on mild elevations in blood pressure before pregnancy may be obtained by careful inquiry into all previous health care encounters by the patient, including visits for contraceptive advice.

Preexisting chronic hypertension secondary to renal disease can be readily diagnosed in patients with type I diabetes mellitus or known systemic lupus erythematosus. In other patients, preexisting renal disease should be suspected when proteinuria is in marked disproportion to the degree of hypertension, especially in multiparous patients[44] and whenever a patient presents with clinical manifestations of preeclampsia at preterm gestation. This suspicion is supported by renal biopsy data showing that 43% of multiparous women presenting with preeclampsia had evidence of preexisting renal parenchymal or vascular disease.[19] It is supported further by follow-up data on patients presenting with preeclampsia before 34 weeks’ gestation, of whom almost 70% had laboratory or renal biopsy evidence of preexisting renal disease.[29]

Because most patients with chronic hypertension have essential hypertension, new-onset proteinuria in patients with essential hypertension makes it easier to diagnose superimposed preeclampsia. This diagnosis requires, however, that an estimation of proteinuria be obtained earlier in pregnancy by quantitative laboratory analysis (e.g., from a 24-hour urine collection). In the presence of preexisting proteinuria in chronic hypertensive disorders of renal cause, a physiologic increase in proteinuria early in the third trimester is difficult to distinguish from pathologic proteinuria caused by superimposed preeclampsia. Under these circumstances, development of other laboratory abnormalities (e.g., thrombocytopenia) may assist the diagnosis. Generally, proteinuria in the severe range—5 g in 24 hours or greater—should be regarded as superimposed preeclampsia in patients with preexisting proteinuria.

Convulsions or coma not related to a hypertensive disorder can develop from neurologic causes; hypertension, proteinuria,

In 2002, the CDC issued replacement guidelines supporting a culture-based rather than a risk-based strategy for GBS prevention.[124] These revised guidelines were based partially on the results of several studies documenting that the incidence of neonatal GBS disease is significantly lower using the culture-based approach, and that a greater proportion of GBS-positive women receive intrapartum prophylaxis under the culture-based approach.[14,126] Patients who arrive in labor with no documented culture results should be managed using the risk-based approach. Intrapartum prophylaxis should be administered by the intravenous route. Penicillin is the agent of choice, with ampicillin an acceptable alternative. There is increasing bacterial resistance to second-line agents such as clindamycin and erythromycin[35,107]; if a patient is allergic to penicillin, this must be noted when the GBS culture is sent to the laboratory so that GBS antibiotic sensitivities can be reported with the culture results. If a patient is allergic to penicillin and not at a high risk of anaphylaxis, cefazolin may be used for intrapartum prophylaxis. If a patient is allergic to penicillin and at a high risk of anaphylaxis, clindamycin or erythromycin may be used as an alternative, but only if GBS culture results document susceptibility to both agents. If culture results document resistance to clindamycin or erythromycin, vancomycin should be used as an alternative.

New avenues for the prevention of neonatal GBS infections are being actively explored. The use of a maternal vaccination against a polysaccharide capsule antigen or a universal antigen of the subtypes of GBS may allow the placental transfer of antibodies that could reduce or eliminate neonatal infection. Other research is directed at the use of hyperimmune and monoclonal intravenous immune globulin as adjuvant therapy or prophylaxis for extremely preterm neonates.

Syphilis

Descriptions of syphilis and its many manifestations have appeared in the medical literature since the 16th century. The introduction of antibiotics 50 years ago reduced the incidence of congenital syphilis to an all-time low of 200 reported cases in 1958. A resurgence of primary and secondary syphilis in recent years has caused a concomitant resurgence in neonatal cases, however.

EPIDEMIOLOGY

From the late 1970s to the mid-1980s, the incidence of primary and secondary syphilis increased slowly. Between 1986-1990, the epidemiology began to shift dramatically. The incidence of reported primary and secondary cases in women increased 240%, peaking at 20.3 cases per 100,000 population in 1990. This increase of reported cases in women seemed to be related to the practice of trading sex with multiple partners to acquire illicit drugs, especially crack cocaine. Because these partners are frequently anonymous, the traditional syphilis control strategy of partner notification is ineffective. Many of the women who became pregnant received little or no prenatal care.[17] By 1997, only 3.2 cases per 100,000 population were reported.[123] The incidence of congenital infection has paralleled this rise and fall. The more recent decline may reflect the renewed attention given to syphilis control programs after the epidemic of the 1980s was recognized (Fig. 23-4). In recent years, there has been an increase in the incidence of primary and secondary syphilis cases in most urban centers in the United States, with an overall increase of more than 20% in 2002.[21] Most of these new cases have occurred in men, however, with the rates among women remaining fairly stable.

CLINICAL MANIFESTATIONS, DIAGNOSIS, AND TREATMENT

After exposure to *Treponema pallidum,* there is an incubation period of 10 to 90 days before the development of primary syphilis. The hallmark of this stage of infection is a painless chancre, which is usually indurated with raised borders and forms at the site of exposure. Although this manifestation is readily apparent in men, it is frequently located in the vagina or on the cervix of women and goes unnoticed. Primary syphilis is a local infection. In contrast, secondary syphilis occurs 4 to 10 weeks later and is a systemic infection, with dissemination of the organism through the bloodstream. The patient may present with a fever, generalized lymphadenopathy, or condyloma lata. The hallmark of this stage of infection is a generalized maculopapular rash involving the trunk, limbs, palms, and soles. This rash is often faint and may be missed. These symptoms and signs spontaneously resolve as the patient enters the latent stage, which may last for years. If untreated, approximately one third of these patients go on to develop tertiary syphilis in 10 to 30 years. This stage is complicated by involvement of the CNS and cardiovascular system and gumma formation.[134]

Clinical diagnosis of "the great imitator" may be difficult, especially in pregnant patients. Antepartum diagnosis relies

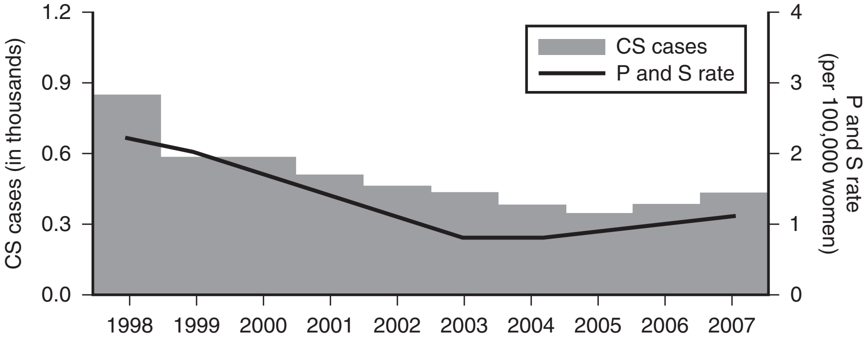

Figure 23–4. Congenital syphilis (CS) cases manifested in infants younger than 1 year old, and rates of primary and secondary (P&S) syphilis among women in the United States, 1998-2007. (*From Cen-*

on serologic screening with nontreponemal tests such as the Venereal Disease Research Laboratory or rapid plasma reagin tests. False-positive results occur in 1% to 2% of the tests and may be caused by recent febrile illness, subclinical autoimmune disease, or laboratory error. Reactive nontreponemal tests are confirmed by specific antibody tests, such as the microhemagglutination assay for antibodies to *T. pallidum* or the fluorescent treponemal antibody-absorption test.[64] Syphilis is treated with penicillin in pregnancy. The number and route of doses depend on the stage of infection at the time of treatment.

CONGENITAL SYPHILIS

Treponemes appear capable of crossing the placenta at any point in pregnancy, and infection can cause preterm delivery, stillbirth, congenital infection, nonimmune hydrops, and neonatal death. Fetal infection can also occur as a result of contact with active genital lesions during labor and delivery. Congenital syphilis causes fetal or perinatal death in 40% to 50% of the infants affected. Spontaneous abortion and stillbirth may be the result of overwhelming infection of the placenta and the resulting nonimmune hydrops.

The earlier literature suggests that transmission occurs in virtually all infants born to mothers with primary and secondary syphilis, although only half of the infants may be symptomatic. The rate of transmission decreases to 40% with early-latent (<2 years) and 6% to 14% with late-latent stages. Even with the appropriate antepartum diagnosis and antibiotic treatment of the mother, 11% of infants may show CNS involvement. Risk factors for congenital syphilis include lack of prenatal care, substance abuse, and African-American race.

Clinical manifestations appearing in the first 2 years of life are referred to as *early congenital syphilis,* and manifestations appearing later are referred to as *late congenital syphilis*. Early disease is associated with nonimmune hydrops, intrauterine growth restriction, hemolytic anemia, hepatosplenomegaly, jaundice, rhinitis (sniffles), maculopapular rash, condyloma lata, bone abnormalities, ocular abnormalities, and CNS involvement. Bone abnormalities such as periostitis and osteochondritis of the long bones are very common. Late congenital syphilis results from untreated or incompletely treated early syphilis. Manifestations include neurologic involvement with mental retardation, eighth nerve deafness, and hydrocephalus; dental abnormalities such as Hutchinson teeth, mulberry molars, and rhagades; and bone abnormalities including a saddle nose, saber shins, and Clutton joints.

PREVENTION

The prevention of congenital syphilis requires prenatal care, antepartum screening, and appropriate antibiotic therapy. The CDC recommendations state that regardless of gestational age, infected pregnant women should be immediately treated with the dose of penicillin appropriate for the stage of syphilis, as recommended for nonpregnant patients.[16] Patients with a history of penicillin allergy may be treated with penicillin after negative skin testing, if available, or penicillin desensitization. Tetracycline is not recommended during pregnancy because of adverse fetal effects. Although erythromycin may be an acceptable treatment for adults, it does not readily cross the placenta and may not treat the fetus as well as penicillin. Maternal follow-up includes monthly nontreponemal serologic testing. An increase in titers or the lack of a fourfold decrease in titers over 3 months indicates a need for retreatment. All patients should be offered counseling and testing for the HIV antibody because of the frequent association between the two infections.

As in nonpregnant patients, the treatment of the early stages of syphilis may precipitate the Jarisch-Herxheimer reaction. The typical fever, myalgia, and headache begin 2 to 4 hours after treatment and last 12 to 48 hours. Uterine contractions, decreased fetal movement, and fetal bradycardia can occur in pregnant patients. Fetal death is more likely to occur during the Jarisch-Herxheimer reaction, when the fetus is also affected.[99]

At birth, the placenta and cord should be examined by dark-field microscopy for treponemes. Neonatal serum should be examined for IgM. Cerebrospinal fluid evaluation and radiography of long bones may be indicated. In an asymptomatic infant at birth, whose mother was appropriately treated and for whom close follow-up can be ensured, a single intramuscular dose of benzathine penicillin is recommended. If the infant has active infection, or neurosyphilis cannot be excluded, the CDC recommends a more extensive evaluation and more prolonged therapy.[16]

Listeriosis

L. monocytogenes is a motile, microaerophilic, gram-positive bacillus that infects primarily pregnant women, newborns, elderly adults, and immunocompromised individuals. Infection with *L. monocytogenes* leads to approximately 2500 serious illnesses and 500 deaths in the United States annually. Maternal infection can lead to stillbirth and premature delivery. Neonatal infection is associated with high morbidity and mortality rates.

EPIDEMIOLOGY

L. monocytogenes is an unusual but important cause of perinatal infection. Cases may be sporadic or occur in epidemics.[28] Many types of mammals and birds harbor the organism, which is viable in manure for long periods. Food and dairy products have been implicated as sources of outbreaks.[22]

MATERNAL DISEASE AND TRANSMISSION

Approximately half of women delivering infants infected with *L. monocytogenes* are asymptomatic before and during labor.[83] When symptomatic, the women present with a nonspecific flulike syndrome with fever, malaise, back pain, and upper respiratory tract symptoms. Diagnosis is most accurately confirmed with blood or amniotic fluid cultures. Broth cultures for listeriosis should be incubated at 4°C to optimize bacterial growth. Premature labor may accompany these findings.

Transmission is generally believed to be hematogenous, with evidence of placental infection. Some neonates may be infected by ascending infection, however, even across intact membranes. It is believed that the fetus is infected first, and the amniotic fluid becomes infected by excretion of contaminated fetal urine. When listeriosis is diagnosed during pregnancy, treatment with high doses of ampicillin has been suggested.[136]

FETAL AND NEONATAL INFECTION

Listeriosis septicemia may cause stillbirth or preterm delivery before viability is reached; however, it does not seem to be a cause of recurrent fetal loss. Prematurity, a birthweight of less than 2500 g, and evidence of fetal compromise are common. Similar to neonates with GBS infections, neonates with *L. monocytogenes* infection have either early (<4 hours after delivery) or late (1 to 6 weeks after delivery) manifestations. Infants presenting with early-onset disease classically have skin lesions, severe respiratory distress, hepatosplenomegaly, and laboratory evidence of sepsis. These infants are more likely to have mothers who were symptomatic before or during labor. Late-onset disease usually affects healthy term infants, with the typical symptoms of bacterial meningitis. Neonatal mortality in early-onset disease ranges from 30% to 60%.[136] In late-onset disease, neurologic sequelae, such as hydrocephalus and mental retardation, are common, and mortality may be 40%.

Chlamydial Infection

C. trachomatis is a species of obligate intracellular bacteria. The organism depends on the invaded cell for its energy supply and destroys the cell with replication. The 15 serotypes of *C. trachomatis* are responsible for three major groups of infection. Serotypes L1, L2, and L3 cause lymphogranuloma venereum; serotypes A, B, Ba, and C cause endemic, blinding trachoma, the most common cause of blindness; and the remaining serotypes D through K are sexually transmitted agents that cause inclusion conjunctivitis, newborn pneumonia, urethritis, cervicitis, salpingitis, acute urethral syndrome, and perinatal infections.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

C. trachomatis is the most common bacterial sexually transmitted infection in the United States, with more than 4 million infections occurring annually. In the past, 5% to 10% of sexually active women in the United States carried *Chlamydia* organisms in their cervix. Certain risk groups, such as young, inner-city women, especially African Americans, have a much higher prevalence. In large, prospective studies, the prevalence in pregnant women has ranged from 2% to 25%, depending on the group studied. Of women with positive gonorrhea cultures, 40% to 60% have a concomitant chlamydial infection. In the current screening system, the prevalence of infection among women 18 to 26 years old is 4.2%.

The anatomic site in the female genital tract that is most frequently infected with *C. trachomatis* is the cervix. The ensuing endocervicitis may be asymptomatic or more commonly associated with a hypertrophic cervical erosion and copious mucopurulent discharge containing a high number of polymorphonuclear leukocytes. *C. trachomatis* is a common cause of tubal infertility.

Cell culture has long been the gold standard for the diagnosis of chlamydial infection. The most sensitive and specific tests currently available are nucleic acid amplification tests, however. The treatments of choice for infection with *C. trachomatis* are azithromycin or doxycycline, with erythromycin, ofloxacin, and levofloxacin as alternatives. In pregnancy, the treatment options are more limited. Azithromycin in a single dose and a 7-day course of amoxicillin are recommended. Doxycycline, levofloxacin, and ofloxacin are contraindicated; recommended alternatives include erythromycins.

ASSOCIATION WITH ADVERSE PREGNANCY OUTCOME

Many studies have investigated the association between endocervical infection with *C. trachomatis* and adverse pregnancy outcomes, including prematurity, PROM, intrauterine growth restriction, and postpartum endometritis. Although some studies report no association of chlamydial infection with delivery before 37 weeks of gestation, others report odds ratios of 1.6 to 5.4. Berman and coworkers[9] attempted to explain part of this discrepancy by noting a tighter association of prematurity and low birthweight with recent chlamydial infection, as shown by the presence of IgM antibodies or IgG seroconversion.

Antepartum treatment of chlamydial infection during pregnancy may improve pregnancy outcome, as suggested by Ryan and associates,[121] who studied 11,544 women, 2433 (21.08%) of whom had a positive *Chlamydia* culture on their first prenatal visit (Table 23-3). Of the women with the positive cultures, 1100 were untreated, and 1323 were treated with oral erythromycin or sulfamethoxazole. If untreated, culture-positive patients had a higher incidence of PROM, birthweight less than 2500 g, and lower incidence of newborn survival.

EFFECTS ON THE NEWBORN

Infants delivered vaginally to a woman with a chlamydial infection of the cervix have a 25% to 60% chance of becoming infected themselves. Manifestations of infection include

TABLE 23–3 Association of Pregnancy Outcome and *Chlamydia trachomatis*

	CHLAMYDIA-POSITIVE		*CHLAMYDIA*-NEGATIVE	
	Untreated	*Treated*		*Total*
PROM	58 (5.2%)	39 (2.9%)	243 (2.7%)	340
Birthweight <2500 g	218 (19.6%)	145 (11%)	1068 (11.7%)	1431
Newborn survival*	1083 (97.6%)	1315 (99.4%)	8973 (98.5%)	11,371

conjunctivitis and pneumonia. Although it is uncommon, *C. trachomatis* has been isolated from infants delivered by elective cesarean section despite intact membranes.

Acute neonatal conjunctivitis in the newborn as a result of perinatal exposure to *C. trachomatis* has been recognized for some time. This organism is now the leading cause of neonatal conjunctivitis. Of infants becoming infected with *C. trachomatis* after exposure during delivery, 17.5% to 46.5% develop this conjunctivitis. When the infants of 230 culture-positive mothers received one of the three prophylactic regimens (silver nitrate, tetracycline 1%, or erythromycin 0.5%), no significant difference in the rate of chlamydial conjunctivitis was noted (20%, 11%, and 14%).[56]

Twenty percent of the infants delivered through a cervix infected with *Chlamydia* may develop pneumonia. Infants do not develop symptoms until 4 to 11 weeks, when they show signs of congestion and obstruction, little nasal discharge, minimal fever, tachypnea, and a prominent staccato-type cough. Chest radiograph reveals hyperinflated lungs with bilateral interstitial infiltrates. Blood gas analysis frequently shows mild or moderate hypoxia. Approximately 50% of these infants have a history of or concurrent conjunctivitis. Most infants recover quickly with oral erythromycin. Other neonatal clinical manifestations of *C. trachomatis* infection include otitis media, bronchiolitis, and perhaps gastroenteritis.

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular parasite with a complex life cycle occurring in three stages: the tachyzoite stage (present during acute infection), bradyzoite stage (present in tissue cysts during latent infection), and sporozoite stage (present in oocysts). Cats are the primary hosts and excrete unsporulated (noninfectious) oocysts in their feces. These cysts sporulate and become infectious in days or weeks. All other animals, including humans, are secondary hosts.

EPIDEMIOLOGY, CLINICAL MANIFESTATIONS, AND DIAGNOSIS

In the United States, 400 to 4000 cases of toxoplasmosis occur annually, and it is a leading infectious cause of foodborne death, after *Salmonella* and *Listeria*. The seroprevalence varies widely based on geography and is 20% to 50% in the United States.[2] There are three main routes of transmission: ingestion of raw or undercooked contaminated meat (the most common route in the United States), exposure to oocyst-infected cat feces, and vertical transmission. Risk factors for infection include owning outdoor cats and cleaning litter boxes, eating raw or undercooked meat, gardening, having contact with soil, and travel to endemic areas. Household cats are usually not a major source of infection, but outdoor cats that hunt rodents may be.

Acute infection occurs after the ingestion of bradyzoites or sporozoites, which are broken down by enzymes and released into the lumen of the gastrointestinal tract. From the lumen, the organisms invade endothelial cells and become tachyzoites. They are widely disseminated to all organs (especially the CNS, heart, and skeletal muscle), where they form tissue cysts (bradyzoites) and persist for the life of the host. In immunocompetent adults, only 10% have symptoms of acute infection, including malaise, fever, rash, splenomegaly, and lymphadenopathy. After acute infection, permanent immunity develops.[6] Reactivation of latent disease can occur in immunocompromised individuals and often involves the CNS.

The diagnosis of toxoplasmosis is problematic because commercial test kits are unreliable. It is recommended that positive results be confirmed in a reference laboratory. The diagnosis of acute maternal infection can be accomplished by the identification of serologic antibodies or *T. gondii* DNA by PCR. Serologic testing is the most commonly used diagnostic method, relying on the detection of IgM or the increasing or high titers of IgG. Various tests have been used to make the diagnosis of fetal infection in utero. Ultrasound evaluation may detect dilation of the cerebral ventricles (the most common ultrasound finding), ascites, hepatomegaly, and intracranial calcifications; however, most (80%) cases do not have ultrasound evidence of infection.[112] Fetal blood samples for IgG and IgM and amniotic fluid for culture and mouse inoculation have been traditionally used for fetal diagnosis. PCR techniques performed on amniotic fluid samples alone provide a sensitivity and specificity equal, however, to those of the older diagnostic tests, with less risk of pregnancy loss.[42]

TRANSMISSION AND NEONATAL DISEASE

The incidence of toxoplasmosis during pregnancy in the United States is approximately 1 in 1000. Intrauterine infection is possible only when the circulating tachyzoites are present to invade the placenta and then infect the fetus. Vertical transmission is limited to primary infection or reactivation in an immunocompromised host. In infection during pregnancy, the organism infects the placenta, and then there is a lag period of 1 to 4 months between maternal and fetal infection. After this period, the placenta acts as a reservoir of infection and transmits viable organisms to the fetus.

The risk of transmission increases with gestational age at the time of infection: It is 10% to 20% in the first trimester, 30% in the second trimester, and 65% in the third trimester.[42,63] The overall risk of transmission in pregnancy is 20% to 50%. The severity of fetal disease is inversely related to gestational age at the time of infection, with disease severity being the greatest if infection occurs in the first trimester. Most infected infants (>80% to 90%) are asymptomatic at birth. The most common clinical finding is chorioretinitis, which progresses in more than 80% of infected individuals by age 20.[54] Other abnormalities in an affected infant can include hydrocephalus, microcephaly, mental retardation, hepatosplenomegaly, jaundice, and lymphadenopathy.

The best information on fetal infection with *T. gondii* comes from France, where the prevalence is approximately 10 times that in the United States. In France, serologic screening is compulsory. If initially seronegative, the pregnant woman is screened monthly for seroconversion. If untreated, the primarily infected pregnant woman has a clinically infected infant 13% to 30% of the time. The inclusion of the spontaneous abortions that may have been caused by toxoplasmosis infection would increase the transmission rate to 46%. Because of the much lower incidence of toxoplasmosis in the United States, routine screening is not recommended.[2]

There are two tiers to toxoplasmosis treatment in pregnancy. For acute maternal infection and an uninfected fetus, spiramycin is used for prophylaxis. This drug prevents organisms from crossing the placenta and infecting the fetus, and decreases the incidence of disease transmission. It is unavailable in the United States, but can be obtained with FDA assistance; clarithromycin and azithromycin are alternatives of unclear effectiveness. When the fetus is infected, treatment is administered with pyrimethamine and sulfadiazine, which work synergistically, and folinic acid. This combination decreases the severity of the disease.

In France, women are now treated with spiramycin when acute infection is diagnosed. At 20 to 24 weeks, prenatal diagnosis is attempted by obtaining amniotic fluid looking for signs of infection, such as positive *Toxoplasma* PCR. If the fetus seems to be infected, pyrimethamine and either sulfadoxine or sulfadiazine are added to the treatment regimen. Daffos and coworkers[32] reported on 746 documented cases of maternal toxoplasmosis treated in this manner. Congenital infection was shown in 42 infants, 39 of whom were diagnosed antenatally. Twenty-four pregnancies were terminated, and 15 were carried to term. Of the 15 fetuses with congenital toxoplasmosis, all but 2 who had chorioretinitis remained clinically well throughout follow-up. Maternal infection occurred earlier during the pregnancy in fetuses that were aborted, and almost all had ultrasound evidence suggestive of toxoplasmosis. Of the remaining 702 fetuses, 3 showed evidence of congenital toxoplasmosis despite negative antepartum studies: 2 with subclinical disease and 1 with meningoencephalitis and chorioretinitis. Prenatal diagnosis can provide practical information in cases in which pregnancy termination is being debated. The initiation of in utero therapy may reduce the severity of the disease in newborns.[43] To prevent maternal disease, pregnant women should be advised to eat only adequately cooked meat, avoid changing cat litter or wear gloves when doing so, wear gloves when gardening, and wash thoroughly all fruits and vegetables before ingestion.

CHAPTER 24

Placental Pathology

Raymond W. Redline

No evaluation of a sick neonate is complete without knowing the status of the organ that has supported the fetus through the preceding gestation—the placenta with its surrounding membranes. The placenta has two opposing functions during gestation. It is the sole source of metabolic substrates for the fetus and its sole protection against noxious external influences, such as genital microorganisms, the maternal immune system, and various types of teratogens. It is important for the neonatologist and the obstetrician to be aware of the specific pathogenic sequences of the placental lesions that compromise these functions.

This chapter does not offer a comprehensive review of placental pathology; the reader is referred to three general references.[4,12,22] Rather, it provides an overview of three topics: (1) the optimal use of the pathology service to obtain useful information, (2) an understanding of specific patterns of placental injury, and (3) clinicopathologic correlation (i.e., which lesions are seen in which clinical situations).

OPTIMAL USE OF PATHOLOGY SERVICE

Any infant requiring the care of a neonatologist should have a placental examination. Because not all placentas are submitted to pathology, every obstetric service needs to have a specific list of situations in which a placental examination is indicated. Box 24-1 provides such a list. Because many sick neonates are transported from other hospitals, there should be a policy to ensure a timely placental examination. The best solution is to transport the placenta in a watertight container along with the neonate to the tertiary care center. For various reasons, the transport of the tissue specimen itself is sometimes impractical. In these cases, the slides and pathology report from the referring hospital should be requested and reviewed by the pathologist at the hospital where the neonate is to be treated. Whenever possible, placentas should be refrigerated immediately after delivery and sent without fixative to the pathology laboratory. Specimens maintained in this fashion remain useful for 7 days after delivery. When refrigeration within 1 to 2 hours of delivery is impossible, placentas should be immersed in 2 to 3 volumes of formalin; placentas can remain in formalin for an indefinite period before examination by the pathologist.

An informed evaluation of the placenta requires that the pathologist be aware of the clinical situation. Some mechanism, usually a form, must be established to convey this information. A proper balance should be struck between a totally open-ended form and a tedious checklist. Figure 24-1 is an example of a form that may be useful. Placental diagnosis requires very few special studies. Even bacterial cultures in cases of suspected chorioamnionitis rarely provide useful information beyond that which is available from placental histology and the infant's blood culture. Fungal stains of the cord and membranes may occasionally be useful for neonatal management. In certain situations, a placental karyotype may be of interest because some data suggest that some cases of intrauterine fetal demise and idiopathic intrauterine growth restriction (IUGR) may be explained on the basis of chromosomal anomalies confined to placental tissues (confined placental mosaicism).[19]

STRUCTURE, FUNCTION, AND PATHOLOGY

Overview

At the simplest level, the placenta is nothing more than fetal blood vessels and surrounding connective tissue enveloped by a continuous layer of epithelium known as *trophoblast* and sitting in a pool of maternal blood called the *intervillous space*; the latter is continuously filled and drained by maternal uterine arteries and veins (Fig. 24-2). The same unit of structure is repeated in an attenuated form in the membranes. Early in pregnancy, the fetal vasculature and maternal intervillous space involute in that portion of the gestational sac destined to become the membranes, leaving a tough shell of fetal connective tissue and the placental trophoblast in contact with the maternal uterus. An understanding of each of these anatomic compartments and their reaction patterns in abnormal pregnancies provides the basis for understanding placental pathology.

Considering the fetal circulation first, the placenta is perfused by a pair of umbilical arteries and drained by a single umbilical vein. Because there is an arterial anastomosis near the umbilical cord insertion site, the fetus is not handicapped if one of the arteries is occluded or absent (single umbilical

BOX 24–1 Indications for Placental Examination

NEONATAL
- Prematurity
- Intrauterine growth restriction
- Unexpected adverse outcome
- Congenital anomalies
- Suspicion of fetal infection
- Fetal hydrops
- Fetal hematologic abnormalities

OBSTETRIC
- Intrauterine fetal demise
- Maternal disease or maternal death
- Signs of maternal infection
- Gestational hypertension
- Oligohydramnios or polyhydramnios
- Antepartum hemorrhage (acute or chronic or both)
- Postpartum hemorrhage
- Abnormal biophysical or biochemical monitoring
- In utero therapy
- Abnormal placenta noted at delivery

Any specific questions about this placenta?

Figure 24–1. Placental data sheet used to transmit clinical history to the pathologist. Each item is widely spaced on the actual full-page form to provide sufficient space for free text.

artery). The vein is the sole supply of oxygenated placental blood for the fetus. It also has the thinnest wall and is the easiest of the three umbilical vessels to collapse. Large arteries and veins branching off from the umbilical vessels transmit blood through proximal stem villi to distal villous units, where gas exchange occurs. Decreased flow in these vessels leads to luminal occlusion (fibromuscular sclerosis) and involution of the distal vascular bed (avascular villi).[42]

This reaction is global in the placentas from stillborn fetuses and focal in live-born infants with placental thrombi or some other cause of upstream vascular obstruction (Fig. 24-3A). Each distal villous unit consists of a central mature intermediate villus and several surrounding terminal villi. Mature intermediate villi have at least one arteriole that directly regulates flow to the terminal villous capillary bed. Obliteration, stenosis, or spasm of these arterioles can have a profound impact on gas exchange.[14] Finally, terminal villi have a capillary bed that in some circumstances can sustain microvascular damage, leading to villous edema[29] or stromal hemorrhage,[13] or undergo reactive hyperplasia (chorangiosis) in response to hypoxia or other local stimuli.[2]

Adequate placental perfusion depends on pregnancy-related increases in maternal intravascular volume and decreases in maternal vascular tone. Maternal conditions such as renal disease, essential hypertension, and collagen vascular disease can cause chronic uteroplacental underperfusion by interfering with these systemic accommodations to pregnancy.[21] To ensure adequate perfusion of the intervillous space, the human placenta has evolved a mechanism for remodeling and enlarging uteroplacental arteries.[35] The placental trophoblast grows down the lumen of these vessels, invades the vascular wall, and replaces the smooth muscle layer with a noncontractile layer of fibrinoid matrix. Failure to execute this sequence compromises perfusion and leaves the uteroplacental vessels susceptible to spasm, degeneration, and rupture. These abnormalities are believed to play an important role in the pathogenesis of preeclampsia and abruptio placentae.[7] It is also important that maternal blood contacts a nonadhesive surface to prevent activation of the coagulation system.

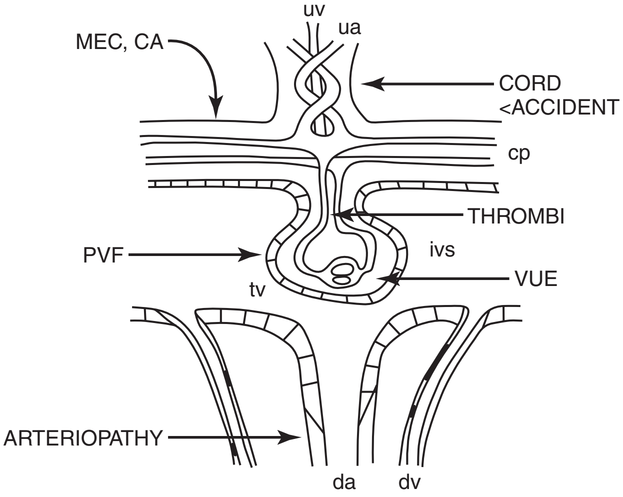

Figure 24–2. Schematic diagram of a functional unit in the placenta, with sites and patterns of injury indicated by arrows. Deoxygenated fetal blood enters the placenta via umbilical arteries (ua) and flows through the chorionic plate (cp) and stem villous arteries before entering terminal villi (tv). Flow into capillaries is regulated by stem villous arterioles. Postcapillary venules combine to form stem villous and chorionic plate veins, which drain into a single umbilical vein (uv) that carries oxygenated blood to the fetus. Maternal blood enters the intervillous space (ivs) via decidual arteries (da) lined with the trophoblast (*hatched lines*) and drains through unmodified decidual veins (dv). Decidual arteriopathy (ARTERIOPATHY) restricts maternal perfusion of the intervillous space. Perivillous fibrin (PVF) coats the villous trophoblast (*hatched lines*), preventing gas exchange. Villitis of unknown etiology (VUE) expands the villous stroma, increasing the diffusion distance. A cord accident (CORD ACCIDENT) compresses the umbilical vessels, causing a global decrease in fetoplacental circulation. Meconium (MEC) and chorioamnionitis (CA) may decrease villous perfusion by damaging fetal vessels in the chorionic plate. Fetal thrombotic vasculopathy (THROMBI) similarly decreases the distal fetal vascular bed.

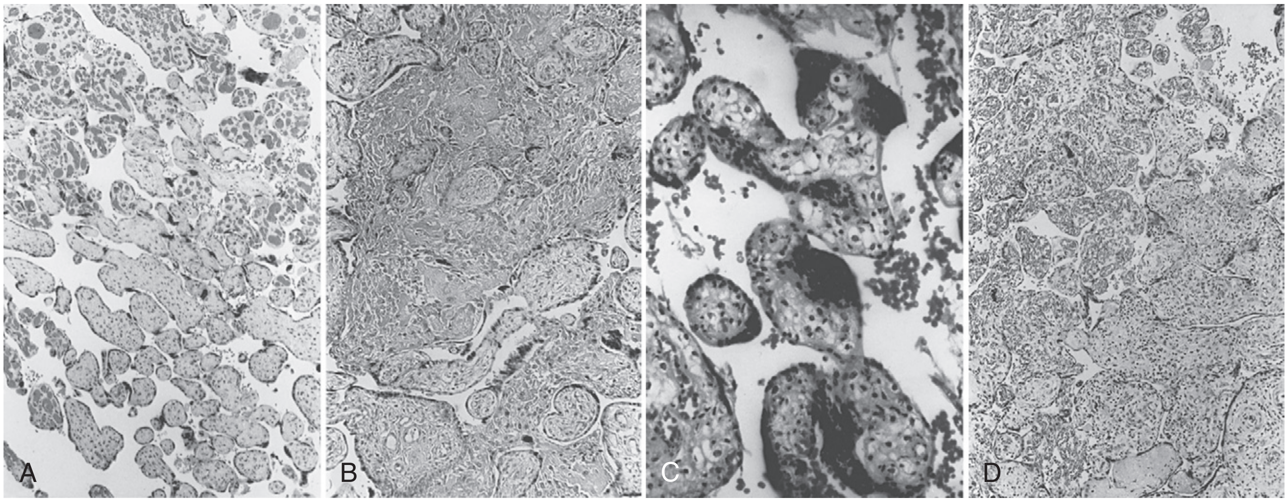

Figure 24–3. Histologic patterns of placental injury. **A**, Fetal thrombotic vasculopathy. Avascular villi (*lower right*) resulting from upstream vascular occlusion. **B**, Massive perivillous fibrin deposition. Fibrin with a proliferating extravillous trophoblast encases terminal villi (especially *upper left*). **C**, Chronic uteroplacental underperfusion (increased syncytial knots). Aggregates of syncytiotrophoblastic nuclei gather at one pole of the villus, leading to attenuation of the remaining syncytiotrophoblastic cytoplasm, maximizing gas exchange. **D**, Villitis of unknown etiology. Maternal T lymphocytes in the fetal villous stroma (*lower right*) lead to edema and fibrosis, which increase the diffusion distance between the maternal and fetal circulations.

Another maternal disorder associated with uteroplacental underperfusion is antiphospholipid antibody syndrome. Data indicate that the anionic phospholipid binding protein annexin-V plays an important role in preventing the assembly of active coagulation factor complexes on the trophoblast cell membrane.[36] Antiphospholipid antibodies have been shown to displace annexin-V from the cell surface, accounting for pathology resembling preeclampsia in affected pregnancies.

Intervening between the fetal and maternal circulations are the tissues collectively referred to as the *interhemal membrane*. These include the syncytiotrophoblast, the trophoblast basement membrane, and the intravillous connective tissue. With increasing maturity, the interhemal membrane becomes thinned, decreasing the diffusion distance for substrates. This thinning is accompanied by an increased formation of syncytial knots. These structures, related to apoptosis and trophoblast turnover, are accentuated further in the presence of hypoxia (see Fig. 24-3C).[26] Because the trophoblast and especially the syncytial knots are in direct contact with circulating maternal blood, they can become dislodged, as attested to by their common presence in the lungs of autopsied cases of maternal death.

Although a mechanism for villous repair and re-epithelialization exists,[31] some of these traumatic events cause villous capillary hemorrhage and fetomaternal transfusion. Cell traffic can also occur in the opposite direction (maternofetal transfusion). When maternal inflammatory cells cross the trophoblastic barrier, they may participate in an allograft-type response against fetal antigens in the villi. This process is believed to occur in villitis of unknown etiology (VUE), and the resulting chronic inflammation increases the diffusion distance (see Fig. 24-3D).[45] Another process increasing the diffusion distance at the interhemal membrane is massive perivillous fibrin deposition ("maternal floor infarction"), an idiopathic accumulation of trophoblast-derived extracellular matrix material that surrounds terminal villi, compromising intervillous circulation and gas exchange (see Fig. 24-3B).[25]

The final placental compartment is the fluid-filled sac of membranes, which must rupture to allow vaginal delivery. Theoretically, membranes may prematurely rupture for one of two reasons: increased luminal pressure, or weakening of the normal structural integrity. Increased pressure can be caused by premature contractions, cervical dilation, or polyhydramnios. Structural integrity may be compromised by trauma, inflammatory responses associated with ascending bacterial infection, or ischemic necrosis caused by maternal vascular compromise. The amniotic fluid contained within the sac is predominantly derived from fetal urine, and changes in fluid volume (oligohydramnios or polyhydramnios) sometimes reflect fetal fluid balance. Chronic uteroplacental underperfusion can lead to fetal hypovolemia, oliguria, and oligohydramnios in the absence of membrane rupture or fetal urinary tract anomalies.[23] Regardless of its underlying cause, oligohydramnios may lead to umbilical cord compression in the short-term,[24] limb deformities in the intermediate-term,[27] and failure of adequate lung growth in the long-term (see Chapter 22).[23]

Placental membranes can also incorporate various exogenous substances suspended in the amniotic fluid, some of which, such as meconium and bacterial products, may damage the membranes and the underlying fetal vessels.[3,17] A third exogenous substance found in membranes is hemosiderin, which can be an indicator of chronic peripheral separation (see later).[30]

Maternal Vascular Pathology

Muscularized maternal arteries supplying the intervillous space are susceptible to stenosis, occlusion, or rupture. Stenosis leads to chronic uteroplacental underperfusion, which is characterized by low placental weight, increased syncytial knotting, and villous agglutination, particularly in the "watershed zones" between spiral arteries.[41] Total occlusion causes villous infarction. Although experimental studies have shown that 20% to 25% of villous parenchyma can be infarcted without acute fetal compromise,[12] these studies fail to account for the impaired status of the remaining placenta in most maternal vasculopathic disorders.

The rupture of maternal arteries (acute abruption) may occasionally be attributed to trauma, but is more commonly an ischemia-reperfusion injury with a secondary rupture of the injured vascular wall. The common association of abruption with vasoactive drugs such as nicotine and especially cocaine is consistent with this pathogenesis.[1,28] Chronic abruption may also occur and manifests pathologically as chronic peripheral separation, which is characterized by diffuse chorioamnionic hemosiderin deposition and placental circumvallation.[30] Most evidence to date suggests that chronic abruption represents venous rather than arterial hemorrhage. Because muscular arteries are incompletely remodeled in preeclampsia, maternal vascular lesions of all types are especially frequent in this disorder. Identical lesions may be seen, however, with idiopathic IUGR, antiphospholipid antibody syndrome, connective tissue disease, diabetes mellitus, chronic hypertension, and chronic renal disease, and in patients with an underlying thrombophilic condition.[21]

Fetal Vascular Pathology

Fetal vessels within the umbilical cord are protected from compression by the cord matrix, a hydrated gel known as Wharton jelly. Several processes lessen this protection: decreased hydration of the matrix, which can occur with chronic uteroplacental underperfusion; torsion-related kinking of the cord because of excessive coiling; and insertion of the cord vessels into the membranes, which leaves them unprotected from trauma.[43] The critical parameters for deciding whether a putative cord lesion can be confirmed pathologically are thrombosis, necrosis, or hemorrhage at the proposed site of occlusion and histologic differences in the cord structures located proximal and distal to the lesion. Large vessels in the chorionic plate and stem villi may occasionally rupture, leading to massive subchorionic thrombosis, a rare, often fatal lesion.[49]

A more common process affecting these vessels is thrombotic occlusion (fetal thrombotic vasculopathy).[42] The factors predisposing to thrombosis are similar to the factors reported for thrombi in other organs: severe inflammation (villitis or chorioamnionitis), toxic damage (prolonged meconium exposure), stasis (chronic umbilical cord obstruction, fetal congestive heart failure), inherited predispositions to clotting (protein C and S deficiencies, maternal antiphospholipid antibodies, factor V Leiden), hyperviscosity (fetal polycythemia), and specific maternal disease states (e.g., diabetes mellitus). Villi downstream from occlusive thrombi are avascular and hyalinized. Adverse sequelae of thrombotic vasculopathy include a decrease in the size of the fetal vascular bed available for gas exchange, coexistent thromboembolic disease in the fetus, and (in rare cases) fetal consumptive coagulopathy with disseminated intravascular coagulation or thrombocytopenia.

Mature intermediate villous arterioles regulate placental resistance to fetal blood flow, the parameter evaluated in clinical pulsed-flow Doppler studies. These arterioles have been found to be numerically decreased in autosomal trisomies[47] and either obliterated or stenosed in patients with severe IUGR.[11,14] A large proportion of placentas with these fetal arteriolar changes also show clinical and pathologic evidence of chronic uteroplacental underperfusion. It is unclear whether fetal arteriolar pathology is the cause or the result of IUGR. Placental arteriolar occlusion could cause placental hypoperfusion and growth restriction, or, alternatively, might simply be the result of hypoperfusion by a sick, volume-depleted infant (see Chapter 14).

As described earlier, placental capillaries can leak fluid (villous edema) or blood (villous stromal hemorrhage), and both lesions have been shown to be associated with adverse outcomes in very premature infants.[13,38] The frank rupture of capillaries is the cause of placental intervillous thrombi and may be associated with hypovolemia; fetal anemia; and a compensatory increase in circulating, nucleated red blood cells.[20] Capillary rupture in some cases may be associated with massive fetomaternal hemorrhage, an important cause of fetal morbidity and mortality.[8] The proliferation of villous capillaries (chorangiosis) is defined by a significant proportion of terminal villi having 10 or more capillary cross sections, and has been associated with chronic villitis, meconium staining, diabetes, and congenital anomalies.[2]

Infection and Inflammation

Acute chorioamnionitis is usually caused by cervicovaginal bacteria that either overwhelm normal cervical host defense systems or gain access to the amnionic cavity after the rupture of membranes (see Chapter 23).[40] The inflammatory response to bacterial infection is predominantly neutrophilic and generally involves the membranes and chorionic plate, but not the chorionic villi. Acute chorioamnionitis is the most common cause of preterm labor.[16] Few delivered infants are septic at birth, however, attesting to the effectiveness of the placenta as a protective barrier.

Histologic features can sometimes help determine the duration of infection in chorioamnionitis.[40] In the initial stages ($<$6 hours), maternal neutrophils marginate in the fibrin just below the chorionic plate (early chorionitis). Later, the neutrophils, predominantly maternal, infiltrate the entire chorionic plate and the full thickness of the membranes (6 to 24 hours). A concomitant fetal neutrophilic response, as manifested by transmigration across the fetal vessel walls, begins in the chorionic plate (chorionic vasculitis) and the umbilical vein (umbilical phlebitis) and is followed by involvement of the umbilical arteries (umbilical arteritis). Changes that occur later, such as fetal neutrophils infiltrating the umbilical cord stroma (perivasculitis) and necrosis of the amnion (necrotizing chorioamnionitis), suggest greater than 24 hours of infection. Finally, perivascular umbilical arcs of calcific debris, glycoprotein, and neovascularization (subnecrotizing funisitis) or a chronic mononuclear component (chronic chorioamnionitis) suggest prolonged infection of days to weeks in duration.[32]

Infants with subnecrotizing funisitis or chronic chorioamnionitis are at increased risk for chronic lung disease secondary to exposure to chronic inflammatory mediators or pulmonary hypoplasia if they have experienced occult membrane rupture with oligohydramnios. Data suggest that the fetal inflammatory response in chorioamnionitis can be deleterious and may be a risk factor for severe neonatal morbidity (bronchopulmonary dysplasia, necrotizing enterocolitis, cranial ultrasound abnormalities, and long-term neurologic impairment).[15,38,39] The above-described patterns are typical for most bacteria. Unusual patterns that can suggest specific organisms are neutrophilic exudates involving the villi and intervillous spaces (suggestive of *Listeria monocytogenes* or *Campylobacter fetus*)[10] and microabscesses on the external surface of the umbilical cord (suggestive of *Candida albicans*).[34]

Chronic placentitis is caused by organisms that enter the intervillous space by means of either the maternal bloodstream or the adjacent uterus. The hallmark of chronic placentitis is destructive, diffuse villitis with fibrosis, calcification, or both.[22] Although villous inflammation is generally emphasized, these infections also involve the chorion, decidua, and other placental regions. This pattern of panplacentitis is typical of fetal infection by organisms of the TORCH group (*Toxoplasma gondii,* rubella virus, cytomegalovirus, and herpes simplex virus), *Treponema pallidum,* other herpesviruses (Epstein-Barr virus, varicella), and a host of other parasitic and protozoan infections rarely seen in the United States. Specific histopathologic features can indicate specific etiologic agents (e.g., increased Hofbauer cells, periarteritis, and necrotizing umbilical phlebitis in syphilis; villous plasma cells in cytomegalovirus; stromal necrosis and calcification in herpes simplex virus; and umbilical cord pseudocysts in toxoplasmosis).

Two other categories of neonatal infection that cannot be evaluated directly by placental pathology are transplacental and intrapartum infections. Transplacental infections spread to the fetus without affecting the placenta, presumably through breaks in the interhemal barrier (maternofetal transfusion). Important organisms in this category include human immunodeficiency virus (HIV), hepatitis B virus, human parvovirus B19, and enteroviruses. Intrapartum infections are acquired by the fetus during passage down a contaminated birth canal and also spare the placenta. Prominent in this category are venereal pathogens such as *Neisseria gonorrhoeae, Chlamydia trachomatis,* and human papillomavirus, and some pathogens associated with neonatal sepsis (e.g., group B streptococci and *Escherichia coli*).

Foci of chronic villous inflammation, such as VUE, are common in term placentas (5% of all placentas), whereas chronic placentitis attributable to the organisms listed earlier is rare (1 to 2 per 100 live births).[45] For many years, it was believed that some new organism would be discovered that could explain VUE, and this may yet happen. Certain features of VUE differ, however, from chronic placentitis of an infectious origin. First, VUE is confined to villi and generally involves only a fraction of the villous tree. Second, the predominant cells in VUE are infiltrating T lymphocytes of maternal origin. Third, VUE can be a recurrent disease associated with maternal autoimmunity, whereas chronic placentitis secondary to infection rarely recurs because of acquired immunity. For all of these reasons, many experts have argued that VUE represents a maternal antifetal immune response, a consequence of genetic differences between the mother and fetus. The main clinical relevance of VUE is its common association with IUGR, which can be attributed to its location in the villous stroma separating the maternal and fetal circulations.

Developmental and Structural Lesions

The final group of lesions to be discussed are gross abnormalities in placental structure. As with structural abnormalities in infants, these placental lesions can reflect either primary maldevelopment or secondary deformations and disruptions. Uterine abnormalities, such as malformations, leiomyomas, or scars from previous surgical procedures, constitute a major cause of abnormal placental development. These developmental abnormalities can be separated into two groups. First are the abnormalities of lateral growth and membrane formation, in which the placenta appears to migrate away from its original implantation site to optimize its blood supply, a process that has been termed *trophotropism*.[4] Trophotropism can lead to bilobation, accessory lobes, membranous cord insertions, and placenta previa, none of which are pathologic by themselves. These placental anomalies can cause problems at delivery, however, by placing fetal vessels at risk for rupture or, in some cases, predisposing to a breech or transverse fetal presentation.

The second abnormality is one of vertical growth. The uterine decidua is believed to regulate the depth of uterine implantation. Prior surgery or other uterine abnormalities can interfere with normal decidualization, leading to uncontrolled placental growth into or through the uterine wall. This pattern, known as *placenta accreta* or *percreta,* most commonly causes postpartum hemorrhage, but in selected cases can lead to uterine rupture.[22]

Another group of structural anomalies are those associated with deformations or disruptions in the fetus. The fetal deformation sequences attributable to amniotic bands (amputations) or prolonged oligohydramnios (clubfoot, pulmonary hypoplasia) are potential complications of early membrane rupture.[23,27] Early membrane rupture and subsequent oligohydramnios are associated with the placental lesion known as *amnion nodosum* (see Chapter 22). Amnion nodosum consists of white membrane excrescences that are the consequence of prolonged contact between the fetal vernix and membrane amnion. Fetal disruptions are caused by in utero ischemia of either a maternal or a fetal origin. Transient interruption of the maternal blood supply early in pregnancy has been correlated with limb and central nervous system anomalies.[5] Such episodes can manifest clinically as chronic abruption and pathologically as a circumvallate placenta (membranes arising inside the perimeter of the placenta, with an associated fibrin rim owing to the peripheral accumulation of blood in a closed uterine environment).[30]

A second cause of fetal vascular disruptions is vascular anastomosis in monochorionic twins (see Chapter 19).[18] Identical twins having a single monochorionic placenta and two separate amnionic sacs (monochorionic-diamnionic) are at the highest risk. Anastomosis can cause sudden circulatory shifts at the time of delivery or, if intrinsically unbalanced, chronic twin-to-twin transfusion. Dichorionic twin placentas, whether from identical or fraternal twins, are almost never affected. Identical twins with only one amnionic cavity (monochorionic monoamnionic) rarely have twin-to-twin transfusion, but commonly have another placental complication—entangled umbilical cords—which can lead to the death of one or both twins.

Although they are present for only a short time, tumors can develop in the placenta. The most common placental tumors are chorangiomas, which are composed of proliferating fetal blood vessels (hemangiomas). Chorangiomas cause pathologic fetal conditions in two ways: by arteriovenous shunting, leading to hydrops fetalis, or by sequestering platelets, leading to disseminated intravascular coagulation.[4,22] Choriocarcinomas (malignant trophoblastic tumors) can arise from the villi of second-trimester and third-trimester placentas and metastasize to the fetus.[6] The placenta can also be a metastatic site for malignant tumors of either the mother (most commonly acute myeloid leukemia, melanoma, and adenocarcinoma) or the fetus (e.g., congenital neuroblastoma).

As mentioned earlier, chromosomally normal infants do not always have chromosomally normal placentas. Placental aneuploidy or confined placental mosaicism, as this phenomenon has been called, can affect all or part of the placenta and is believed to explain some cases of idiopathic IUGR and intrauterine fetal demise.[19] The morphologic sequelae of this phenomenon, if any, have not yet been established. Candidate lesions include the dysmorphic villi described in cases of triploidy or monosomy X.

BOX 24–2 Clinicopathologic Correlation

PRETERM LABOR
- Acute chorioamnionitis
- Abruption (acute or chronic)
- Chronic uteroplacental underperfusion
- Idiopathic chronic uterine inflammation

INTRAUTERINE GROWTH RESTRICTION
- Chronic uteroplacental underperfusion
- Villitis of unknown etiology
- Abruption (chronic)
- Fetal thrombotic vasculopathy
- Perivillous fibrin

INTRAUTERINE FETAL DEMISE
- Large placenta with delayed villous maturation
- Massive fetomaternal hemorrhage/intervillous thrombi
- Hydrops fetalis (any cause)
- Multiple placental lesions

NEONATAL ENCEPHALOPATHY
- Abruption (acute)
- Umbilical cord accident
- Rupture of fetal vessels

CEREBRAL PALSY (PRETERM)
- Severe villous edema
- Chorionic vessel thrombi
- Multiple placental lesions

CEREBRAL PALSY (TERM)
- Fetal thrombotic vasculopathy
- Severe fetal chorioamnionitis
- Abruption (chronic)
- Multiple placental lesions

CLINICAL CORRELATION

The various anatomic, physiologic, and pathologic reaction patterns discussed earlier can be placed in clinical context by determining their relative frequency in common obstetric and neonatal disease syndromes (Box 24-2). Such generalizations may be misleading in considering individual patients, but they can be useful in considering the range of possible diagnoses and causes in a particular case.

Preterm labor is most commonly associated with pathologic evidence of acute chorioamnionitis.[16] In many cases, it can be difficult to determine whether infection develops before or after the onset of labor. Because chorioamnionitis generally triggers labor relatively rapidly, most cases that develop after prolonged membrane rupture likely represent secondary infection.

Most of the remaining cases of preterm birth fall into three groups: placental abruption, either acute or chronic; chronic maternal underperfusion, with increased syncytial knotting; and uterine structural anomalies without associated placental abnormalities (e.g., cervical incompetence).[48] Less commonly, preterm birth may be associated with idiopathic chronic inflammation (lymphoplasmacytic deciduitis, decidual perivasculitis, or eosinophilic chorionitis).

IUGR may be constitutional, relating to small maternal size, malnutrition, or an anomalous fetus. When IUGR is caused by uteroplacental disease, two clinicopathologic pictures predominate: chronic uteroplacental underperfusion, with or without associated hypertension,[21] and VUE, generally in the absence of hypertension.[37] Other, less frequent uteroplacental causes of IUGR are fetal thrombotic vasculopathy, chronic peripheral separation, and massive perivillous fibrin deposition (“maternal floor infarction”).

Intrauterine fetal demise, particularly at or near term, is often difficult to explain pathologically. One group at increased risk are fetuses with clinical entanglements or pathologic lesions of the umbilical cord. These lesions may predispose to chronic or intermittent episodes of umbilical venous obstruction that can be diagnosed by pathologic criteria.[33] Another distinct subgroup at risk are infants with delayed villous maturation leading to decreased placental reserve and susceptibility to transient hypoxic events.[50] The prototype for this subgroup is an infant of a diabetic mother. A less common, but important cause of stillbirth is massive fetomaternal hemorrhage, which is manifested in the placenta by intervillous thrombi and increased circulating nucleated red blood cells.[8] Fetomaternal hemorrhage and its accompanying anemia can cause congestive heart failure and hydrops fetalis. Hydrops of any cause can lead to stillbirth. Other causes of hydrops identifiable by placental examination include chronic infections such as human parvovirus B19, toxoplasmosis, and syphilis. Finally, occasional stillbirths show evidence of more than one of the following lesions: chronic uteroplacental underperfusion, fetal thrombotic vasculopathy, VUE, and massive perivillous fibrin deposition.[9]

The placental findings that have been associated with long-term neurologic impairment in preterm infants are severe villous edema, chorionic vessel thrombi associated with histologic chorioamnionitis, and multiple placental lesions.[38] Neonatal encephalopathy and cerebral palsy in term infants can be related to acute birth asphyxia, chronic intermittent hypoxia, chronic uteroplacental disease, or various combinations of these problems.[39] The placental findings associated with acute asphyxia include acute abruption, acute occlusive umbilical cord accidents, and rupture of fetal vessels (i.e., tears in the villous parenchyma or umbilical or chorionic vessels). Subacute or chronic intermittent stress, often related to clinical or pathologic umbilical cord problems (see earlier), is commonly accompanied by an increase in nucleated red blood cells in the placental circulation.[46] Long-term neurologic impairment in term infants has been specifically associated with fetal thrombotic vasculopathy and other processes affecting large fetal vessels, such as severe fetal chorioamnionitis, meconium-associated vascular necrosis, and VUE with stem villous vasculitis.[44] Another important risk group are those infants with multiple placental lesions.[39]

SUMMARY

The placenta is the link that connects the clinical status of the neonate with underlying maternal and fetal disease processes. Careful evaluation of this organ not only provides useful diagnostic, prognostic, and therapeutic information, but also enhances overall understanding of perinatal biology. Communication among neonatologists, obstetricians, and placental pathologists brings together distinct pieces of a puzzle that none can fully solve alone. Through this process, meaningful explanations of the reasons for adverse perinatal outcomes and their chances of recurrence can be provided for concerned physicians and family members.

SECTION IV

The Delivery Room

CHAPTER 25

Anesthetic Options for Labor and Delivery

McCallum R. Hoyt

The goal of modern-day obstetric anesthesia practice is to provide the patient with analgesia as she requests it. That goal assumes that her choice is appropriate to the labor process, is appropriate to the current conditions as evaluated by the obstetric provider, and has as little impact on the fetus as possible. Depending on preferences, the patient may approach her labor with prepared responses to modify pain perception, or plan to use systemic medications or nerve blocks, or some combination of these. How and whether a mother's choice has an impact on fetal well-being and neonatal outcome is the focus of this chapter, and a discussion of the newer anesthetic techniques as the neonatologist should understand them is included. This chapter also reviews some established pain relief approaches and some popular alternatives currently in vogue.

LABOR PAIN CHARACTERISTICS AND CHALLENGES

The gold standard of labor analgesia is the neuraxial block. The term *neuraxial block* encompasses epidural, spinal, and combined spinal-epidural nerve blocks that can be administered only by clinicians trained in anesthetic methods. With modern-day techniques, doses are reduced to such low levels that an analgesic state that diminishes pain and minimizes the effect on other sensory pathways such as touch and proprioception is possible, and often the goal. The lower doses result in less absorption into the maternal bloodstream than with past techniques, and in some cases, levels are nondetectable. The end result is an unaffected mother with adequate pain relief that allows her to participate actively in her labor and a fetus with little, if any, medication exposure. All procedures carry some risk, however, and dosing methods vary widely across the United States such that a fetal or neonatal effect from the medications used is possible.

Research into the sensation of pain has shown a very complex process that is far from fully understood. To appreciate the complexity of providing analgesia to a laboring patient and understand better successes and expectations when doing so, a considerably abbreviated and simplistic discussion of pain is in order. A clinically useful classification of pain is to define it as being visceral or somatic. Stated simply, *visceral pain* originates from the viscera and is often described as cramping, dull, and steady. *Somatic pain* is related to nonvisceral structures and is commonly described as sharp, intermittent, and well localized. In terms of labor, the pain experienced in the first stage is predominantly visceral, with some somatic components as the uterus contracts and the cervix dilates. The second stage is more somatic in nature, with little visceral involvement.[42]

The challenge with adequately managing labor pain is understanding that its very dynamic nature requires adaptation of pain techniques. Pain can evolve rapidly over a relatively short time, changing not only in intensity, but also from a visceral to a somatic source. To add to the challenge, not all medications are effective for all types of pain. Local anesthetics block nerve conduction and are effective where the nerves responsible for pain transmission are accessible. In labor, the nerves transmitting the pain are well described, and most can be reached with a needle, making some form of nerve block with a local anesthetic a common choice. Opioids are very effective for visceral pain, but are of little value for somatic pain. Systemic opioids can aid a patient reasonably well during the first stage of labor, but have little effect if used during the second stage.

Despite the proven safety and efficacy of lower dose neuraxial techniques, not all obstetric patients wish to use them, and practitioners are not always available to perform the procedures. Also, an obstetric patient may not be a reasonable candidate for a neuraxial block for myriad reasons. As a result, many of the tried and true approaches for managing labor pain are still commonplace in obstetric suites in addition to some interesting alternative therapies.

TECHNIQUES THAT MODIFY PAIN

Although nonpharmacologic techniques do not alter the actual transmission of pain sensation, they attempt to alter the person's perception and response to it, with some measured success. Many of these approaches require preparation beforehand, and their effectiveness is subject to several variables. As a result, studies comparing Lamaze, hypnosis, and other nonpharmacologic methods to nerve blocks and medications are difficult to evaluate.

The assumption held by proponents of alternative pain management techniques and many expectant mothers is that nonpharmacologic techniques to control pain without the use of medications and nerve blocks do not have any adverse effect on the neonate and are the safest and healthiest choice for the mother and her infant. Clinical studies have not proven this assumption to be true. Although most techniques are as benign as they appear, some can carry unintended consequences if not performed properly, making this pertinent knowledge for the well-informed neonatologist.

Natural Childbirth and Other Nonpharmacologic Approaches

NATURAL CHILDBIRTH

Natural childbirth is a technique that was first defined by Lamaze in the 1950s and that increased in popularity in the 1960s as an alternative to the heavy sedation that was often used at the time. The technique of controlled breathing and focal points to stay in a relaxed state during a contraction is based on the theory that one can modify the sensation of pain and one's response to it. Building on the popularity of the Lamaze approach to labor pain, the Bradley technique was introduced in the 1970s as a variant and incorporated the woman's spouse as her active coach. Today, the term *natural childbirth* applies to any breathing technique that the mother uses during labor to cope with pain and avoid pharmacologic methods.

Is natural childbirth an effective way to manage pain during labor? There is some objective evidence that Lamaze training as originally practiced is associated with β-endorphin elevations, which may help alter pain sensation.[8] What is not always appreciated by individuals who teach and couples who use this technique to prepare for labor is that incorrect performance can have negative consequences. Maternal and fetal $P\text{CO}_2$ levels are positively correlated.[2,29] If the mother deviates from the defined breathing technique and hyperventilates during her contractions, her $P\text{CO}_2$ levels decline as a result.[28] This situation has two effects. First, maternal hypocapnia causes uterine vasoconstriction, reducing blood flow to the fetus; second, the fetus also develops hypocapnia in response to the maternal hypocapnia. As the fetal $P\text{CO}_2$ decreases, the fetal oxyhemoglobin dissociation curve shifts leftward, causing a reduction in fetal oxygenation and setting the stage for hypoxia and metabolic acidosis.

If during the first stage of labor fetal acidosis develops, it worsens during the second stage, especially if that stage exceeds 1 hour.[1,2,40] When hypoxia and a base deficit are present during the second stage of labor, it is difficult to reverse in utero.[40] The result is a neonate who is in need of resuscitation. This series of events does not occur in every case, but the bradycardia associated with this scenario can resemble that of cord compression and result in obstetric maneuvering.[29] Effective analgesic techniques have been shown to improve these conditions if applied before the second stage.[1,29]

Several factors have come to bear on modern-day childbirth courses that teach the Lamaze or Bradley techniques and the information that is provided. Couples are no longer willing to take the full 6-week training course. Instead, weekend courses are offered that try to present all the information in 2 days. This alternative makes it nearly impossible to practice and learn the pain-controlling techniques that Lamaze and Bradley described. In addition, information on all available forms of pain relief options is variable, owing not only to some potential personal biases by the instructor, but also to the instructor's knowledge of what is available at maternity units in the area. As a result, couples may approach labor with a rigid plan that does not take into consideration informed alternatives for pain management should the fetus show signs of compromise.

A significant percentage of patients who attempt a drug-free birth eventually request some form of relief, and defer to the labor nurse, who makes suggestions based on the usual practice for that unit. The pain relief often comes in the form of a systemic medication, but when available, a neuraxial block such as an epidural is the request of choice. A mother often views resorting to any form of analgesia, especially an epidural, as a failure on her part. It has been shown, however, that when mothers resort to a neuraxial block, it is as a result of labor that is frequently longer and associated with higher pain scores, and the mothers are unprepared for the intensity of the process.[20]

HYPNOSIS

Self-hypnosis for labor and delivery enjoys a devoted following among individuals for whom the process has been successful, but it is a technique that not many individuals can use. It requires time for training and practice, and it is not a choice for individuals with only a weekend set aside for learning it. The process has been well described[33,47] and essentially allows the mother to enter a self-induced, trance-like state. Her partner sends her "cues" by touch that signal changes in the process. These cues have been agreed on beforehand and practiced.

The proponents of hypnosis offer a criticism of the Lamaze method. They claim that Lamaze teaches mothers to focus on the start of a contraction to begin breathing.[21,63] As a result, the mother is always focusing on the initiation of pain and the length of a contraction. With hypnosis, there is no need to focus on anything but the images that constitute the individual's trance, so there is no need to adjust to a contraction. Proponents claim they feel relaxed and more capable of pushing.[63]

Only a few evidence-based studies have been published in recent years, and the study populations all are small. A Cochrane database review reported a meta-analysis of 14 studies that examined alternative methods for labor pain management against traditional methods, and reported that hypnosis seems to be effective in modulating the perception of labor pain. Of the techniques reported, hypnosis and acupuncture were found to reduce the need for other medications and more invasive techniques. No other alternative methods were effective.[51] The studies looked only at the avoidance of pharmacologic interventions, however, and not neonatal outcome. As noted previously, if improper breathing techniques are used during the natural childbirth process, there may be some deleterious effects on the fetus.[1] Hypnosis does not require changes in normal breathing patterns, which poses the question whether there is any impact on the intrauterine environment during labor and fetal well-being.

WATER BIRTH

The water birth movement holds that submersion for labor, delivery, or both reduces the sensation of pain. It also holds that birthing from one water environment into another is less stressful for the infant. There are no substantive studies supporting this claim. Similar to most alternative methods, almost everything reported in the literature is anecdotal. A Cochrane database review article found no differences in outcome between the water birth method and other pharmacologic and nonpharmacologic pain control methods.[32] A randomized, prospective study found no benefits in terms of fewer requests for other forms of analgesia, improved maternal outcomes, or neonatal outcomes, with one notable exception: There was a significantly higher incidence of the need for neonatal resuscitation.[7] Another retrospective review chose to exclude births in which the Apgar scores were less than 7, and then reported no adverse effects.[41] Of the many criticisms of this method for pain management, one of the most often cited is the potential for infection, but this has not been supported by the literature.[7,32,41]

ACUPUNCTURE, SALINE INJECTIONS, AND TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

Acupuncture, saline injections, and transcutaneous electrical nerve stimulation (TENS) have most often been used to address the issue of low back pain during labor, and not labor pain management in general. In controlled trials, acupuncture has been shown to be beneficial,[51] but time-consuming and without consistent results.[50,60] In addition, the study sizes have been small, indicating that more research is needed.[51]

TENS for the management of back pain involves the placement of electrodes over the sacrum. A low electrical pulse is transmitted that modifies the sensation of pain. This method has been shown to work well for low back pain in general, but does not lessen the request for other analgesics in general labor pain management. TENS has also been shown to work well as an adjuvant with other, more conventional modalities for labor analgesia.[58,61] None of these techniques seem to have any negative effect on the neonate.

Obstetric Nerve Blocks

Obstetric nerve blocks are invasive procedures to achieve analgesia that are performed by the obstetric provider managing the labor. Only two nerve blocks are used in obstetric practice, and these are used for different goals. The paracervical block provides pain relief in the first stage of labor, whereas the pudendal block is used for analgesia during the delivery portion of the second stage.

PARACERVICAL BLOCKS

The purpose of the paracervical technique is to block pain transmission via the visceral afferent fibers near the dilating cervix. This objective is reached by injecting local anesthetic lateral to the cervix at the vaginal fornices. There are many small variations of the technique, and in the United States lidocaine is the local anesthetic of choice. Bupivacaine is not recommended because of its low threshold for cardiovascular toxicity.

In use since the early part of the 20th century, the paracervical technique became a popular mode of pain control in the 1950s and 1960s. Reported to provide moderate to excellent pain relief over 75% of the time, the most common complication of the paracervical block has been a high incidence of fetal bradycardia (up to 40%).[38] Although the bradycardia has been described to be of a short duration and usually without adverse sequelae, fetal deaths have been reported.[45] Theories to explain this adverse effect include rapid absorption of the local anesthetic by the fetus to toxic levels and direct injection of the fetus. One study reported that the umbilical arteries, and to a smaller extent the uterine arteries feeding the placenta, constrict after anesthetic injection. The bradycardia resolved when the vessels had relaxed and approached their baseline state. There was no difference in the technique, however, and no explanation as to why this phenomenon occurred in the first place.[39]

Paracervical blocks are currently less commonly performed for labor pain in the United States than two decades ago. Although they are virtually unheard of in obstetric units where neuraxial blocks for labor analgesia are available, they are useful when neuraxial blocks are unavailable, and are reported to have a low complication rate with a neonatal outcome no different from neonates exposed to systemic opioids.[24] There are few well-conducted studies to assess adequately the true risks of paracervical blocks on the fetus, however.[45]

PUDENDAL BLOCKS

Pudendal blocks are reserved for the delivery phase of the second stage of labor and are most typically used when an operative delivery with forceps is planned. The pudendal nerves are blocked using a transvaginal approach. The obstetric provider injects 5 to 10 mL of local anesthetic at the site of the attachment of the sacrospinous ligament to the ischial spine. A significant potential complication of the procedure is maternal intravascular injection, so aspirations are frequently performed. Despite the avoidance of maternal injection and the typically short interval between injection and delivery, blood levels of the local anesthetic may be found in the neonate for 4 hours after delivery. Neurobehavioral examinations have not shown an impact, however.

Systemic Medications

Two classes of drugs are commonly used by obstetric providers in modern practice for labor pain management with systemic medications: opioids for pain relief and sedatives to relax and reduce anxiety. Under emergent surgical conditions, anesthesiologists use other classes of drugs, but these are not reviewed in any detail here. When considering the effect of any medication on the fetus, it is worth noting whether that medication has produced a cerebral effect on the mother. If so, that medication has the properties to cross the lipid blood-brain barrier, and is likely to cross the placental barrier to reach the fetus because the necessary transport mechanisms are the same.[65] The extent to which a fetus is exposed depends on many factors, however, such as the drug's pharmacokinetic and pharmacodynamic properties, the dose, and the mode of delivery. This section reviews a few of the pharmacologic principles pertinent to medication choices and fetal exposure. A more complete discussion can be found in Chapter 38 or in any major pharmacology text.

PHARMACOKINETICS, PHARMACODYNAMICS, AND THE FETUS

Three pharmacologic characteristics are considered when weighing whether or not a medication has the properties to enter the maternal circulation from its primary site of administration and then leave that circulation to cross the placenta: (1) how much of the drug is in the ionized versus the nonionized state as determined by its pH, (2) whether it has lipophilic or hydrophilic tendencies, and (3) whether or not it prefers to bind to protein. A medication that is ionized cannot cross a membrane barrier. If a drug's pH is physiologic ($pK_a = pH = 7.4$), 50% of the drug is ionized, and 50% is nonionized. For the purposes of discussion, local anesthetics are a class of weak bases ($pK_a = 7.6$ to 9.1), so they are more ionized when exposed to physiologic pH. The ratio by which a local anesthetic is ionized as opposed to nonionized in the circulation depends on the pH of the drug. A local anesthetic with a pK_a of 9.1 is mostly ionized, and more stays in the maternal circulation than a local anesthetic with a pK_a of 7.6. Because the nonionized portion of a drug can cross a membrane barrier, the amount that crosses equilibrates itself into ionized and nonionized forms when in the fetal circulation. If the fetal pH is lower than the maternal pH because of acidosis, more of the drug converts to the ionized form while in the fetal circulation and cannot return to the maternal circulation. If maternal exposure to the medication persists, more of the drug passes from the mother to the fetus, and increasing amounts accumulate in the fetal circulation. This phenomenon is called *fetal ion trapping,* and has been associated with some of the deleterious effects produced by medications in a compromised fetus.

Of the other pharmacodynamic properties mentioned, drugs that possess lipophilic properties, as opposed to hydrophilic properties, are more capable of crossing lipid-rich membranes. Most medications used in obstetrics are lipophilic, but to varying degrees. Fentanyl and sufentanil are lipophilic opioids, but sufentanil is much more so. As a result, epidural doses of sufentanil more readily leave the epidural space to enter the maternal circulation than fentanyl.

Protein binding is the third important pharmacologic principle. A drug that binds with protein molecules remains in the maternal circulation because when bound, it becomes a bulky molecule. Only the unbound drug is free to cross a membrane and produce an effect. Excluding active transport mechanisms, it is the unbound, nonionized portion of a lipophilic medication that can cross a membrane barrier to produce an effect.

The pharmacokinetic effects of metabolism and elimination are another regulator of how much or even whether a drug exerts an effect on the fetal brain. Most medications undergo extensive metabolism into inactive metabolites in the maternal circulation. As a result, very little, if any, effect may be found. An example of a rapidly metabolized medication is succinylcholine, a depolarizing muscle relaxant. This medication is metabolized to benign metabolites by pseudocholinesterase in the maternal plasma and has a half-life of about 90 seconds. As a result, nothing gets to the fetus. If a drug is metabolized into an active metabolite in the maternal system and crosses the placenta, or is activated in the fetal system, that metabolite can have fetal effects. Such is the case with normeperidine, the active metabolite of meperidine.

A useful measurement that helps estimate fetal medication exposure is the ratio of the umbilical vein drug concentration to the maternal vein drug concentration (UV:MV). A ratio of 1 (UV:MV = 1) means that the amounts of medication in the umbilical vein equal the amounts in the maternal vein. A low ratio means that a small amount has crossed the placenta to reach the umbilical vein. The nondepolarizing muscle relaxants used in general anesthesia are highly ionized, hydrophilic compounds that do not cross the membrane barrier. Their UV:MV ratios tend to be on the order of 0.1. Table 25-1 lists the UV:MV ratios of some common anesthetics.

TABLE 25–1 Placental Passage of Commonly Used Anesthetic Medications

Drug	Umbilical Vein to Maternal Drug Vein Ratio
Induction Agents	
Thiopental	1.08 (range 0.5-1.5)
Ketamine	0.54 (range 0.4-0.7)
Propofol	0.7
Etomidate	0.5
Nondepolarizing Neuromuscular Blocking Agents	
Pancuronium	0.19
Vecuronium	0.11
Opioids	
Morphine	0.92
Meperidine	0.81 (may exceed 1 after 2-3 h)
Fentanyl	0.57
Sufentanil	Levels too low to measure in humans
Butorphanol	0.84
Nalbuphine	0.97

Adapted from Glosten B: Anesthesia for obstetrics. In Longnecker DE et al, editors: *Principles and practice of anesthesiology,* 2nd ed. St. Louis, 1998, Mosby, p 1996.

Even if the umbilical vein levels are significant, they may not be great enough to produce any significant neurobehavioral effect because two more protective barriers exist to shield the fetal brain from medication exposure. Approximately 40% to 60% of any medication entering the fetal circulation passes through the liver first, and then travels through the inferior vena cava to the heart and out into the circulation. The mature or nearly mature fetal liver can metabolize most drugs, and this first pass through the liver buffers the fetal brain from exposure.[9] Additionally, the unique fetal circulation dilutes most of any drug as it travels into the general circulation, and this dilutional effect can be quite protective of the fetal brain.[9]

The dose and the mode of administration have an impact on how much medication enters the maternal circulation for eventual fetal distribution. Although intravenous administration achieves the highest maternal blood levels, all blocks and injections distribute some level of the drug into the maternal circulation, and they differ markedly from one another. From the greatest to the least effect on maternal blood levels, drug administration modes have the following ranking[9]: intravenous > paracervical > intramuscular > epidural > spinal. Maternal local anesthetic levels after a spinal delivery are so low as to be clinically irrelevant.

SEDATIVES

The routine use of heavy sedatives in the active phase of labor has markedly diminished from half a century ago, making it unlikely that a neonatologist would be caring for a neonate with a recent exposure. In modern practice, the primary purpose of sedatives is to help the parturient rest during a prolonged latent phase of labor, as a sleep aid before starting an induction in a few hours, or as administered during a cesarean section either to an anxious patient or before the induction of a general anesthetic. Other than in the cesarean section scenario, enough time usually passes between administration and delivery so that any significant drug amounts clear the maternal and fetal circulations. The classes of medications most often used today are benzodiazepines, barbiturates, and phenothiazines.

Benzodiazepines are most likely encountered in an acute situation either because of maternal self-administration or from the anesthesia provider during a cesarean section. The two most commonly encountered benzodiazepines are diazepam and midazolam. Midazolam has a low UV:MV ratio, so it does not cross to the fetus well at all, making it essentially without clinical effect when given acutely. The most common use of midazolam is during a cesarean section that is unplanned. It is given by the anesthesia provider, and although it is a very good anxiolytic, it causes maternal amnesia, which impairs the mother's recall of the delivery if given beforehand. Midazolam is usually reserved for highly anxious patients, and most providers attempt to delay administration until after delivery. Diazepam has a high UV:MV ratio that reaches 1 within minutes and can increase to 2 within hours.[65] Metabolites are active and can remain in the system for 8 days. When given in the intrapartum setting for eclamptic seizures, diazepam can cause hypotonia, hypothermia, and respiratory depression in a neonate. It was previously thought that diazepam caused oral cleft malformations when used long-term during the first trimester, but more recent prospective studies do not support this assertion. Regardless, diazepam is not as commonly prescribed by obstetric providers as it once was, and its use is usually limited to the acute management of maternal seizures.

The most common barbiturate used outside of the anesthetic setting is secobarbital (Seconal). It has been popular for decades as a sleeping aid, and has a long safety record in terms of the fetus. Although the drug crosses the placenta, it is immediately exposed to the liver and rapidly distributed to other fetal tissues. The result is that brain tissues are rarely exposed to drug levels that are high enough to have a sedative effect from a single dose.[2] It is only with repeated doses that levels can be achieved that have a significant effect within the fetus. Barbiturates have a known antianalgesic effect, however, so administration during labor makes little sense. Another barbiturate that is used less commonly now is phenobarbital. It was previously proposed to prevent intraventricular-periventricular hemorrhage in preterm infants, but this has not been substantiated. Thiopental is a barbiturate used as an anesthetic induction agent, most commonly in the emergent setting and under conditions of compromised uterine perfusion. It is highly protein-bound and has a low UV:MV ratio. What manages to cross the placenta quickly binds to fetal albumin leaving very little in the free form to have a significant clinical effect in the neonate. Although not a barbiturate, propofol is now commonly used as an induction agent over thiopental. The two have similar profiles as far as neonatal effects are concerned.

Phenothiazines have long been used in conjunction with opioids to reduce the side effects of opioids and produce mild sedation. Only two are used because they have minimal effects on the fetus: hydroxyzine (Vistaril) and promethazine (Phenergan). These medications are commonly given in conjunction with a systemic opioid such as meperidine.

OPIOIDS

The definition of an opioid is any natural, synthetic, or semisynthetic compound that acts on the same receptors as morphine and produces similar effects. Agents that stimulate opioid receptors are known as pure agonists and include morphine, meperidine, and fentanyl. Agents that act on only some of the receptors and may even block action on others are known as agonist-antagonists and include nalbuphine and butorphanol. Pure antagonists block action on all receptors and are not considered opioids, but can reverse their actions. Naloxone defines this class.

Opioids do not block the transmission of pain, but rather stimulate receptors to alter the perception of pain and one's response to that perception. For that reason, opioids are considered incomplete analgesics. There are three known opioid receptor types and a possible fourth on which these drugs act.[46] The μ receptor provides the most complete analgesia, but also most of the known side effects of opioids, such as pruritus, nausea and vomiting, euphoria, dysphoria, and respiratory depression to the point of apnea. The κ receptor mediates less intense analgesia because of what is known as a "ceiling effect." The dose-response studies performed early in the investigation of medications that stimulate this receptor determined that the curve stopped rising at a particular dose. This flattening of the dose-response curve means that more of the drug does not produce more of an expected effect. This "ceiling effect" holds not only for analgesia, but also for respiratory depression. No other side effects seem to be associated with this receptor type. The μ and κ receptors have been divided into multiple subgroups. The δ receptor mediates the effects of the endogenous endorphins, especially as they act on the spinal cord. The final receptor, named the σ receptor, may be responsible for some of the side effects occasionally seen with some opioids. The existence of this receptor is dubious, however. Box 25-1 lists some opioids commonly used in labor and their classifications.

Opioids seem to be more effective on visceral pain than somatic pain. As a result, they are more useful during the first stage of labor, which tends to be visceral in nature, than the second stage, which is more somatic.[42] Because all opioids can cross the placenta and produce an effect in the fetus, systemic opioid use has traditionally been limited to the first stage so that the opioid is metabolized from the fetus before delivery. Not only has the selection of opioids expanded over the years, but also the thoughts on how they can be delivered. Intermittent intravenous and intramuscular administrations are still the mainstay on most units, but now intravenous patient-controlled analgesia (IV-PCA) is being offered. Most authors agree that because of the neonatal effects, IV-PCA should be reserved for situations when a regional technique is either unavailable or contraindicated.[35]

Several reports in the literature describe the IV-PCA technique with meperidine, fentanyl, nalbuphine, alfentanil, and remifentanil.[30,34,35,48] Neonates of mothers who use this technique should be watched for signs of sedation, respiratory depression, and low oxygen saturation.

Opioid Agonists

Morphine, meperidine, fentanyl, sufentanil, alfentanil, and remifentanil are opioid agonists that may be used on the obstetric unit. Morphine is the only naturally occurring agonist; if used at all during labor, it is used early. The reason is that not only is morphine more depressive to the neonate than any other opioid, but it also may depress uterine contractions, making it a questionable choice for labor management.[46]

Meperidine (Demerol) is a synthetic opioid. This opioid is the one most commonly used systemically, and there is evidence that it enhances the effacement and dilation of the cervix.[26,59] It has atropine-like properties that can produce tachycardia and myocardial depression in the mother. Also, when injected into the epidural or spinal space, it can produce a block similar to local anesthetics.[4,18] For this reason, there are case reports that describe the use of meperidine in this manner in patients with a documented allergy to all forms of local anesthetics.

BOX 25–1 Opioids Commonly Used during Labor

AGONISTS
- Natural
    - Morphine
- Synthetic
    - Meperidine
    - Fentanyl
    - Sufentanil
    - Alfentanil
    - Remifentanil

AGONIST-ANTAGONISTS
- Nalbuphine
- Butorphanol

When used to provide systemic analgesia, meperidine is traditionally dosed in such a way as to limit fetal exposure before delivery. The drug's duration of action is 2 to 4 hours, with a half-life of 3 to 4.5 hours. Based on that, and knowing that intramuscular administration requires about 45 minutes to 1 hour to absorb and have an effect, meperidine is not given unless delivery is expected within the hour or beyond 3 hours. Estimate of delivery time is an imprecise science, however, and sometimes the neonate is delivered during peak exposure. Even so, the need for naloxone to reverse the depressive effects is uncommon in this scenario. This drug has been used in the IV-PCA format, and protocols are published describing its administration through the first stage and even during the second stage up to delivery.[48] Although some reports state a significant incidence of depression requiring treatment,[35] others do not.[48] In any case, it would probably be best to observe neonates exposed to this form of analgesia closely. Meperidine is metabolized to an active metabolite called normeperidine. The fetal liver is capable of metabolizing meperidine into its active metabolite, or it can cross the placenta and accumulate. The half-life is 15 to 40 hours, so its neurologic and depressive effects can be evident for some time after delivery.

Several commonly used opioids are analogues of meperidine: fentanyl, sufentanil, alfentanil, and remifentanil. Although only fentanyl and sufentanil are used for anesthetic nerve blocks, fentanyl, alfentanil, and remifentanil have been used systemically in the obstetric setting. All these meperidine analogues are lipid soluble and can cross the placenta. They are rapidly metabolized by the first pass through the liver to inactive metabolites, however, making any depressive effects uncommon when these drugs are given as intermittent intravenous boluses. Because of its pharmacokinetic properties, remifentanil is so short-acting that it can be used only in a continuous infusion mode. In one study, fentanyl was injected as a maternal intravenous dose of 1 μg/kg just before the start of cesarean section, and no neonatal depressive effects were detected.[9] Conversely, a study in Finland described the use of a special bed that noninvasively monitors for respiratory depression in the neonate, and claimed that the neonates exposed to intravenous fentanyl experienced more depression than the neonates exposed to paracervical blocks.[31] The population was very small, however, and the study authors suggested that this new monitoring tool needs further evaluation.

Fentanyl has been used in the IV-PCA format,[27,44] as have alfentanil[27] and remifentanil,[19,34,62] with mild neonatal depression a common occurrence. This mode of administration is increasing, and obstetric providers find it a more acceptable alternative to intermittent injections when anesthetic services are limited or neuraxial blocks are contraindicated. Remifentanil, in particular, may be well suited to the IV-PCA format because its half-life is only 4 minutes. Generally, oxygen supplementation and observation are all that is required for the neonate after such exposure.

One final note about opioid agonists: All of them are associated with the suppression of fetal beat-to-beat variability, which returns to normal as the drug is eliminated, suggesting a causal effect.

Opioid Agonist-Antagonists

All medications in the opioid agonist-antagonist category stimulate the κ receptor and have a "ceiling effect" on respiratory depression, as previously described. This information gives providers a sense of safety. The "ceiling effect" also applies to analgesic capabilities, however, making this class of drug limited in its effectiveness. The two most commonly used formulations on obstetric units in the United States are nalbuphine (Nubain) and butorphanol (Stadol). Both medications produce sedation in the mother and degrade to inactive metabolites, and although both cross the placenta, the fetal effects seem limited.[9] Nalbuphine reduces fetal beat-to-beat variability, however, and can produce a sinusoidal pattern when used.[30]

These two medications are markedly different in how they act on the μ receptor. Although butorphanol has essentially no effect on the μ receptor, nalbuphine actively blocks it. As a result, it can be used in small doses in lieu of naloxone to counter μ receptor side effects such as pruritus. The danger with nalbuphine is that it can place a narcotic-addicted patient into acute withdrawal at doses commonly used for labor analgesia. It can do the same to addicted neonates.[9] Caution should be exercised when using this medication if there is any indication of narcotic abuse in the mother.

Because of the sedative and respiratory depressive effects of these drugs and the inability to produce complete analgesia, heavy intrapartum use can lead to a situation in which maternal hyperventilation during a contraction is followed by hypoventilation as the contraction recedes. This condition produces predictable results for oxygen and carbon dioxide levels of the mother and the fetus. The end result can be significant fetal acidosis that begins during the first stage and worsens during the second.[1,2,28,29,40]

Opioid Antagonists

Although other antagonists exist, naloxone (Narcan) is used on obstetric units almost exclusively. This medication blocks the action of an opioid on all of the receptors and is commonly used to reverse the side effects and adverse effects of excessive amounts. It has a short half-life (30 to 45 minutes), which means that repeated boluses may be necessary in some instances. Naloxone is not a benign drug and has been known to cause pulmonary edema and cardiac failure in some situations, so caution should be exercised when using it. It crosses the placenta, so it reverses any opioid effect in the fetus. As with nalbuphine, it is not a medication that should be given to a mother with a narcotic addiction. It produces withdrawal in the mother and in the addicted fetus.[28]

NEURAXIAL BLOCKS

Any variety of epidural, spinal, or combination thereof falls under the general term of *neuraxial block*. These nerve blocks are performed by an anesthesia provider and are the preferred techniques for cesarean deliveries because maternal airway management is avoided, sensorium is unimpaired, and little or no medication reaches the fetus. Neuraxial blocks are commonly offered to laboring patients after labor is established. Their versatility makes them the ideal choice; how dense or sparing the block is can be determined by which medications are used and in what manner they are dosed. In most situations, only an analgesic state is desired, but occasionally a denser block more closely resembling an anesthetic is preferred. This technical nuance defines two very different goals for the anesthesia provider. An anesthetic is designed to remove all sensation—pain, temperature, touch, vibratory sense, proprioception, and motor ability. The goal of an analgesic is to eliminate only the sensation of pain, leaving all other components intact. Logically, higher doses are more likely to produce the anesthetic state, whereas lower doses may produce only an analgesic state. This can be a difficult goal to achieve because individual patient needs vary greatly.

Techniques

How the most basic neuraxial blocks are administered has evolved over time to include several variations, of which the combined spinal-epidural and the patient-controlled epidural analgesic are just two. This section does not describe all aspects of these procedures in detail, but neonatologists should be aware of their most fundamental facts. A more in-depth description may be found in any anesthesia text.

LUMBAR EPIDURALS

The lumbar epidural technique may be performed with the patient in either the sitting or the lateral position. To block the nerves that transmit labor pain (T12-L2), the back is examined for the L4-5, L3-4, or L2-3 interspaces. A placement at any of these three levels produces the necessary nerve block. When the catheter is appropriately positioned, and the initial dose of medication is administered, it is common practice to begin a continuous infusion. This technique is called the *continuous epidural infusion* and has almost completely replaced the intermittent bolus technique. There are numerous drug combinations, concentrations, and infusion rates cited in the literature, but the prevalent trend today is to use dilute local anesthetic concentrations in an attempt to achieve an analgesic state. This practice also improves the safety of the technique because lower doses mean there is less of a chance of a deleterious effect on either the mother or the fetus should the catheter migrate into either a vessel or the spinal space.

PATIENT-CONTROLLED EPIDURAL ANALGESIA

A variation of the continuous epidural infusion technique is the patient-controlled epidural analgesic. With this method, the patient is given the ability to administer a bolus to herself as needed. Some anesthesia providers prefer to maintain a baseline infusion, whereas others do not. There is some debate on whether a baseline infusion is necessary, but should one be started, it is usually at a lower rate than that used for the conventional continuous epidural infusion. Studies have found that when patients are given control over their epidurals, they tend to be more sparing of the medication and use 35% less on average.[35]

INTRATHECAL INJECTIONS (SPINALS)

The word *spinal* is often replaced by the more accurate terms of *intrathecal* and *subarachnoid*. A spinal performed for labor analgesia can preserve temperature, touch, proprioception, and mobility while providing analgesia. The procedure is the same as that described for an epidural with the exception that a 25- to 27-gauge styletted needle is used, and a catheter is not left behind. The stylet is not removed until a "pop" is felt as the needle passes through the dura into the cerebrospinal fluid. When the stylet is removed and the presence of cerebrospinal fluid confirmed, the medication is injected, and the needle is removed.

Intrathecal injections are associated with the lowest maternal blood levels of all the analgesic methods used, resulting in clinically irrelevant fetal exposure. The most commonly used opioids for the induction of labor analgesia are highly lipophilic and travel to the μ receptors within the central nervous system. As a result of this spread, maternal somnolence and even respiratory depression have been reported with small doses as the opioid acts on these receptors.[13] Managing this maternal complication inappropriately has an effect on the fetus, but there is no direct effect on the fetus from the opioid as a result of the intrathecal injection. Although intrathecal opioid injections have been tried as the sole labor analgesic, they are not effective beyond the first stage, and they may not last long enough for the labor. Additionally, should there be a need for an operative delivery or cesarean section, another anesthetic procedure would be required. To resolve this issue, spinals were combined with epidurals.

COMBINED SPINAL-EPIDURALS

With the combined spinal-epidural technique, an epidural and a spinal are performed at the same interspace so that only one local injection is required. The spinal needle may go through or under the epidural needle, or there is a special needle adapted for this technique that is available. When the epidural tip is situated in the epidural space and before the catheter is threaded, the spinal portion is performed. After the intrathecal injection, the spinal needle is removed, and the epidural catheter is threaded into the epidural space, and the epidural needle is removed. This procedure allows for a rapid analgesic response (the spinal), which can be sustained through the epidural catheter.

This method has increased greatly in popularity, but not all anesthesia providers believe it is the best procedure for all parturients. There are some parturients for whom it is better suited, such as a rapidly progressing multiparous patient who might not be offered anything otherwise. The biggest detriment with the technique is that the epidural catheter may be untried; if a problem arises, there may not be time to test and then administer medication. Although the continuous epidural infusion and patient-controlled epidural analgesic have a slower onset of pain relief than a combined spinal-epidural, the epidural catheter is tried and functional should there be a sudden change in delivery plans.

Maternal Risks and Benefits

BENEFITS

Every study that compares the analgesic effect achieved with a neuraxial block against any other form of analgesic technique, whether it is pharmacologic or nonpharmacologic, documents a superior result. When done properly, these blocks allow the mother to relax and conserve her energy for the second stage of labor where she should have enough motor preservation to participate in that process. They also prevent the maternal hyperventilation often seen in response to pain and all the potential sequelae on the fetus associated with lower maternal P_{CO_2} levels.[28]

Although the medications used with an epidural can eventually be found in the maternal circulation, measured blood levels are low. The current trend is toward opioid and very dilute local anesthetic concentrations, which further help to keep maternal blood levels to a minimum. As a result, mothers typically show very little, if any, systemic effect from the administered medications, and such low maternal levels usually indicate very limited exposure to the fetus.[9]

Several studies have shown that neuraxial blocks improve uterine and intervillous blood flow, provided that maternal hypotension is avoided. Two of the earliest studies documenting this result were published by Hollmen and colleagues[14] and Shnider and coworkers.[49] Hollmen and colleagues[14] used an intravenous radioactive marker to document improved intervillous blood flow after an epidural. They compared intervillous blood flow results in two epidural study groups, each using a different local anesthetic, against a nonepidural control group.[14] They found that intervillous blood flow decreased by 19% in the control group, but improved by 35% and 37% in patients receiving the epidurals. Shnider and coworkers[49] examined the physiologic stress response to labor by measuring catecholamine levels before and after epidural initiation in active labor. They showed that with an effective epidural, norepinephrine levels decreased by 19%, and epinephrine levels decreased by 56% from preblock levels. These findings were significant not only because of the reduced catecholamine effect on uterine contractions, but also because catecholamine reductions maintain uterine blood flow better.

MATERNAL SIDE EFFECTS

Common side effects of neuraxial blocks are hypotension, postdural puncture headache, and some degree of motor block that prohibits ambulation. Hypotension is common after any neuraxial block, but frequently more severe after a spinal. It is also more common after an anesthetic dose than an analgesic one because the sympathectomy produced by the higher dose of local anesthetic is more profound. If the hypotension is allowed to persist untreated, there are significant consequences to the mother and the fetus. It would be below the standard of care, however, not to treat hypotension when it occurs. As a result, the episodes are brief and generally without any sequelae.

A postdural puncture headache can be debilitating to the point of preventing the new mother from leaving a supine position and performing any normal activities. The headache is the result of the dura being intentionally or unintentionally punctured during the course of a neuraxial procedure with resulting cerebrospinal fluid leakage. Most headaches are time limited and resolve within 2 weeks of the puncture if no action is taken. Most patients agree to an epidural blood patch for rapid relief, however, with excellent results.

Although the goal of an analgesic dose is to avoid a motor block, some level of weakness is likely if a local anesthetic is part of the dosing mixture. As a result, the policy at many institutions is to confine the parturient to her bed after the neuraxial block is placed. Although the idea of a "walking epidural" was popular some time ago, studies showed that getting out of bed did not improve the progress of labor, and many providers have stopped offering this option.

Other irritating side effects occur primarily because of the opioid used and include pruritus, nausea and vomiting, sedation, and urinary retention. All are due to stimulation of the μ receptor (opioid) and dissipate with time. The only hazardous opioid-induced side effect is respiratory depression, and although it is rare, health care providers should always be alert for its presentation.

MATERNAL RISKS

The anesthetic and nonanesthetic literature is full of discussions of documented and potential maternal risks resulting from neuraxial blocks. Although some are uncontested, such as epidural hematoma formation or nerve damage, others are quite fantastic, such as a reduction in the IQ of the neonate. The wide-ranging list of maternal risks include unintentional intrathecal or intravascular injection, longer labor, increased incidence of operative delivery, maternal temperature elevation, too high of a level that can cause respiratory depression, and an increased risk of cesarean section. Risks of backache, nerve damage, infection with possible abscess formation, epidural or subdural hematomas, and arachnoiditis are postdelivery problems, and the reader is referred to any obstetric anesthesia text for a full discussion there. This section considers only the maternal risks that are documented or have undergone scientific scrutiny, and pose a potential problem for the fetus or neonate.

Cesarean Sections

In 1989, a study was published that claimed epidurals increased the incidence of dystocia in primiparous patients and were causing the cesarean section rate to increase.[57] Although there were several problems with the sentinel study, subsequent studies were published with the same claim, and soon restrictions were placed on epidurals and the timing of their placement because many believed epidurals were directly increasing the cesarean section rate, particularly for dystocia. All these studies suffered from the same limitation, which was that patients were either allowed to choose their analgesic mode or, if randomized, allowed to change to the other analgesic choice, resulting in a high crossover rate to epidurals. What these studies actually showed was that patients with difficult, protracted labors demanded epidurals for the superior pain relief, and investigators believed it would be unethical to deny patients in pain access to it. Over time, ethically designed, randomized, controlled studies were performed and published, as were impact studies. They eventually showed that there was no causal effect of epidurals on the cesarean section rate for dystocia.[10,11,23] It is now understood that dysfunctional labors are prolonged and very painful, and are associated with a greater cesarean section rate. When women are faced with long, painful labors, they choose the most effective means of pain relief available, and that is often some form of neuraxial block. Epidurals may be associated with dysfunctional labors and, as a result, cesarean sections, but they do not cause this situation.

Labor Prolongation

Prolongation of labor has long been blamed on neuraxial blocks. This claim is still undergoing some debate. Available data indicate not only that neuraxial analgesia in early labor does not increase the cesarean delivery rate, but also that it provides better analgesia and results in a shorter duration of labor than systemic analgesia.[23,64] As for second-stage prolongation, it is now generally acknowledged that there is an increase of about 15 minutes on average.[10,23] There has been only one study claiming a longer second stage of approximately 1 hour.[56] The question now is whether a 15-minute increase in the length of the second stage is clinically significant. The earlier studies that looked at epidurals and their effects on the fetus showed that epidurals had a protective effect in that the fetal acid-base balance was better preserved.[40] This result was less likely to occur if the mother did not have effective analgesia. As a result of this finding, the American College of Obstetricians and Gynecologists (ACOG) changed its recommendation on time-limited pushing. ACOG currently recommends that if an epidural is in place and there are no signs of fetal compromise, the second stage should be allowed to continue and the patient reassessed at regular intervals.

Operative Vaginal Deliveries

Neuraxial blocks have been associated with an increased need for operative vaginal deliveries. When studies report on the overall incidence of forceps deliveries and epidurals, there is no question that the incidence increases when an epidural is in place. There are many reasons why an obstetrician chooses a forceps delivery, however, and those reasons are not always obstetrically defined. An obstetrician may request an epidural placement rather than perform a pudendal block if he or she believes that forceps are indicated for delivery. This may be because the obstetrician is uncomfortable performing a pudendal block or prefers the superior analgesia an epidural provides. As a result, the birth is recorded as a forceps delivery under an epidural.

Much of the literature on this topic does not specify the reasons for the use of forceps, but for the few studies that report the indication, no increase in the use of forceps for obstetric indications is observed.[10,23] Impact studies have also been helpful in that they document that the presence of a new epidural service does not increase the incidence of forceps deliveries for obstetric reasons, which strongly suggests that they have no effect.[10] Until more well-controlled studies are performed in which the indication for the forceps delivery is documented, however, it will be difficult to determine precisely what the risk is, or whether one actually exists.

Maternal Temperature Elevation

Elevated maternal temperature has been reported as a risk of neuraxial block and has been a topic of debate. Within the specialty of anesthesiology, this finding has been difficult to explain. It is well documented that when a patient receives an epidural anesthetic for a surgical procedure, including a cesarean section, the patient's core temperature decreases.[16] The reason is that an anesthetic dose produces a significant sympathectomy that causes a general vasodilation below the level of the block, which allows an increased heat loss into the immediate environment. Studies performed in the 1990s showed, however, that under the conditions of a low-dose analgesic epidural, maternal temperature elevates after about 5 hours of very stable body temperature. Specifically, when the temperature elevation begins, it rises at about 0.07°C per hour and then stabilizes at about 39.5°C. Most often, no other clinical signs of maternal infection are present, but the elevated maternal temperature is frequently enough to prompt a sepsis workup on the neonate. Studies that looked at the neonatal results reported that there was no increased incidence of sepsis despite the maternal temperature elevation.[10,23] As a result, many neonatal units have adjusted their policies to require other clinical indications besides maternal temperature before a neonatal sepsis workup is initiated.

Inadvertent Injections and Excessively High Levels

Inadvertent intrathecal or intravascular injections when a neuraxial block is performed can have a serious impact on the fetus. The epidural space is a vascular and a potential space. Possible catheter or needle complications include placement into a vessel or through the dura into the intrathecal space. Unrecognized misplacement with subsequent injection of a large amount of local anesthetic can cause maternal hypotension, seizures, and cardiovascular collapse from an intravascular injection or respiratory compromise that may lead to apnea from an intrathecal injection. When an unrecognized intravascular injection occurs, the acute insult to the fetus seems to be due to the maternal hypoxia that develops during the seizure or arrest and not to the high levels of anesthetic in the maternal system, although some of it is sure to cross over. When a high block happens because of improper dosing or an unrecognized intrathecal injection, maternal respiratory muscles become paralyzed, and inadequate respirations, including apnea, can occur. If this condition is not recognized and treated, the maternal arrest has obvious consequences on the fetus. Both of these complications are exceedingly rare and preventable with attention to good technique.

Benefits and Potential Risks for the Fetus

Much of the literature on neuraxial blockade has focused on the maternal effects. Many laypersons and some health care providers assume that for every negative maternal effect, there must be an associated negative fetal or neonatal effect. The literature does not support such a presumption, however. Studies that have examined the fetal and neonatal effects typically report on the presence or absence of base excess to determine the recent intrauterine environment, the intrapartum fetal heart rate (FHR), the Apgar scores, and a host of neuroadaptive examinations. These neuroadaptive examinations often require operator training and have varying abilities to determine any prolonged effect on the neonate from an intrapartum event or medication. The Neurologic and Adaptive Capacity Score (NACS) may be unable to distinguish between hypoxic and drug effects in a neonate.[3] This section discusses the effects of neuraxial block on the fetus and neonate as defined by the aforementioned indicators and concludes with a brief review on breast feeding.

ACID-BASE BALANCE

A notable benefit a fetus gains from a neuraxial block in the mother is that she no longer hyperventilates in response to painful contractions. As mentioned earlier, hyperventilation in response to pain causes maternal $P\text{CO}_2$ levels to decline and results in a maternal respiratory alkalosis. Because fetal levels follow maternal levels, the same respiratory alkalosis develops in the fetus, causing a leftward shift in the fetal oxyhemoglobin curve and less oxygen to bind with fetal hemoglobin.[29] This situation sets the stage for fetal hypoxia and a metabolic acidosis that often worsens during a prolonged second stage. With a functioning neuraxial block in place, these events are less likely to occur, and studies have consistently shown an improved fetal acid-base balance when an epidural is used.[1,29,40]

Neonatal base excess measurement at delivery is believed to reflect best the intrauterine environment just before delivery, and studies comparing epidurals against systemic medications or nonmedication labor management methods have documented that neonatal base excess levels stay within normal limits more consistently with epidural use than they do with other techniques.[23,40] Other findings are that amounts of meconium are less or similar on delivery, and Apgar scores are comparable or improved when a functioning epidural is in place. These findings support further the idea of a better intrauterine environment and less stress on the fetus with effective neuraxial blocks present.[11,15,43]

FETAL HEART RATE

What effect a neuraxial block has on FHR is confusing. Fetal bradycardia, which occurs in approximately 10% to 12% of cases receiving an epidural, has been a long-recognized phenomenon. It typically begins 5 to 10 minutes after the epidural medication is administered and lasts for approximately 2 to 7 minutes before returning to baseline. It is usually significant enough to initiate intrauterine resuscitative measures, but rarely leads to an early delivery. Apgar scores are typically normal on delivery.[53] This phenomenon has been described with all commonly used neuraxial medications and techniques. The significance of this finding is unclear.

The use of neuraxial opioids can also produce an effect on FHR. Loss of beat-to-beat variability can be attributed to neuraxial opioids, but this side effect is also seen with systemic opioids and agonist-antagonist opioids.[52] Comparison of analgesic techniques shows that FHR changes are more common with systemic medications.[9] Also, the need for naloxone at delivery is more common in neonates whose mothers received systemic opioids during labor than in neonates whose mothers received neuraxial opioids. Although studies show that the neuraxial opioid effects on FHR are temporally limited, when very high doses are delivered repeatedly to the epidural space enough can be absorbed systemically by the mother and cross the placenta. This situation can result in high levels in the neonate at birth and require the use of naloxone.[22] As a result, anesthesia providers should be careful with the timing and use of neuraxial opioids during the second stage of labor.

BREAST FEEDING

A frequent claim made by people opposed to the use of epidurals is that this mode of pain relief temporarily or permanently damages the neonate's ability to breastfeed. Precisely how this damage occurs has never been elucidated, and the hypotheses that have been proposed and seemed plausible have not withstood scientific scrutiny. A common theory is that medication used in the epidural space enters the maternal circulation, reaching such high levels that enough crosses to the fetus where it remains in the neonatal circulation after delivery and produces an adverse effect. The other common hypothesis is that high maternal systemic concentrations from epidural injections seep into the breast milk and affect the neonate.

One study examined residual drug presence in the colostrum and neonate when the mother was given intravenous fentanyl (1 μg/kg) just before cesarean section. This design purposely exposed the fetus to higher maternal blood levels than would be achieved with epidural fentanyl. Blood samples were taken from the neonate at delivery and at 2-hour intervals up to 10 hours. Colostrum samples were also collected at the same time intervals. At 10 hours, there were no detectable levels in either the colostrum or the neonate, indicating that any breast-feeding difficulties would not be due to a residual drug effect.[54] Another study examined the immediate effect on breast-feeding behaviors in neonates whose mothers received epidurals with fentanyl and low-dose local anesthetic concentrations versus neonates whose mothers received nothing at all, not even a local anesthetic for the episiotomy. Cord blood samples were collected for bupivacaine and fentanyl analysis, breast-feeding behaviors were documented, and an NACS evaluation was performed at 2 and 24 hours. Although detectable, the medication levels were low, and neither the breast-feeding behaviors nor the NACS results differed between groups, indicating no medicinal effect.[37] Anecdotally, some of the patients who had undergone labor without an epidural were so exhausted after delivery that they were unable to breastfeed, which was not the case with patients who had an epidural.

Different postpartum management behavior of patients may affect breast feeding in mothers who had neuraxial blocks.[12] Although there are numerous reasons why mothers and neonates do not succeed at breast feeding, the current peer-reviewed literature does not support the premise that neuraxial techniques have any effect on the abilities of the neonate to do so.

DELIVERY MODES AND ANESTHETIC TECHNIQUE

When a mother presents for labor management, and delivery is not imminent, an important role for the obstetric team is to support whatever pain-relieving choices she makes as long as there is no perceived harm to her or her fetus. Choices are not always well informed, however, or circumstances dictate a change in labor management that conflicts with the mother's desires. A morbidly obese patient who has a difficult airway and a questionable FHR tracing should not pursue the water birth she planned, but be counseled on oxygen supplementation and placement of an epidural in anticipation of a possible emergency cesarean section. Labor is one of the most dynamic natural events in medicine, and what may begin as a routine process can change very rapidly. As a result, analgesic techniques and management plans need to be adaptable. This section outlines some of the anesthetic-based considerations the anesthesia provider faces when a spontaneous vaginal delivery is no longer a probability.

Operative Vaginal Delivery

There are two types of operative vaginal deliveries: the vacuum extraction and the forceps delivery. The vacuum extraction cannot be performed until the head is very low in the pelvis. The extractor is generally a pliable Silastic cup, and the application is well tolerated by the mother so that additional analgesia is unnecessary even if none was used for the labor. Some local anesthetic to the perineum in anticipation of an episiotomy may be all that is required.

Forceps application and delivery generally require some level of analgesia, and often the obstetric provider either requests a neuraxial block or performs a pudendal block. Four levels of forceps delivery are described, but at present the two most commonly performed are low and outlet forceps deliveries. The placement of the forceps blades is very stimulating, and it is only in a dire emergency that an obstetric provider should perform such a delivery without some form of anesthesia in place. A pudendal block is a reasonable choice and can be performed in less time than a spinal or epidural can be administered. Neuraxial blocks offer more complete pain relief, however, and compared with an epidural or combined spinal-epidural, can be extended to a higher level should the need arise.

Cesarean Section

Cesarean sections can be performed electively, urgently, or emergently. The circumstances under which one occurs generally dictate the form of anesthetic used. Most anesthesia providers prefer not to use a general anesthetic because of concerns with the maternal airway and potential aspiration. In the general surgical population, the incidence of encountering a difficult airway is about 1 in 2300 to 3200. The chance that one will encounter a difficult airway in the obstetric population is about 10 times higher, an incidence quoted to be about 1 in 300.[5] Several factors contribute to this number. The changes of pregnancy itself cause edematous airways resulting from fluid accumulation.[36] Add to this the time spent in labor, especially after many Valsalva maneuvers in the second stage, and what was once a normal airway can become swollen and easily obstructed with attempts at intubation.

Other changes that contribute to maternal risk during induction include changes of the pulmonary system, gastrointestinal system, and body habitus over the course of the pregnancy. These changes and the often emergent nature of an obstetric procedure may result in failed airway management, with or without aspiration. Greater than 90% of maternal deaths worldwide that are directly anesthesia-related are due to complications from airway management when performing a general anesthetic, with more than 75% reported to be preventable or the result of substandard care.[55] For most anesthesia providers, neuraxial anesthesia is the approach of choice whenever possible.

NEURAXIAL ANESTHESIA

In an elective or urgent situation, some form of neuraxial block is the anesthetic of choice, assuming that there are no existing contraindications (Box 25-2). If an epidural is already in place, it is easy to change medications to a more

BOX 25–2 Absolute Contraindications to Neuraxial Blocks

- Severe hypotension
    - Hypovolemia
    - Sepsis
    - Hemorrhage
- Infection at the site
- Coagulopathy or thrombocytopenia
- Maternal refusal

concentrated, faster onset local anesthetic. Opioids may or may not be added. Attention must still be paid to the dosing technique because moving the patient onto the operating bed may dislodge or shift the epidural catheter; test doses and aliquoted dosing amounts are still in order. If an epidural block is not in place, and the need to proceed with the cesarean section is urgent or emergent, the preferred approach in most units is to perform an intrathecal injection or possibly a combined spinal-epidural. These techniques give a faster onset and limit the medication exposure of the fetus. All neuraxial techniques have been shown to result in better neonatal parameters than when a general anesthetic is performed.[25]

GENERAL ANESTHESIA

At what level of surgical urgency a neuraxial block should not be attempted or abandoned is always a topic for debate. This decision should never be made lightly because of issues with the maternal airway, effects of anesthetics on uterine tone, and the potential impact on the fetus. There are absolute contraindications to performing a neuraxial block as well (see Box 25-2), and when one is present, it directs the decision making. Neonatologists present at a nonelective cesarean section consider a general anesthetic as a potential risk for resuscitation in the neonate. The literature supports the clinical observation that under the conditions of a short incision-to-delivery time frame, and with the current pharmacologic developments of short-acting anesthetics, the impact is small. The anesthetic agents that are the most commonly used are discussed subsequently.

Before the induction of a general anesthetic, the anesthesia provider usually gives the mother one or more agents to reduce the risk of aspiration. The most commonly used agent is citrate, which is an antacid taken orally just before induction. Other agents that may be given instead of or along with citrate are some form of H_2-blocker such as ranitidine, and metoclopramide. None of these medications have been shown to have an impact on the fetus.[9]

Because it is only during the induction phase and a short period of maintenance that the fetus is exposed, the anesthetics of concern are induction agents, a rapid-onset neuromuscular blocker such as succinylcholine, nitrous oxide, a volatile agent, and occasionally opioids. The previous discussion on general pharmacologic properties and the UV:MV ratio should help gauge the potential impact on the fetus. Table 25-1 shows the UV:MV ratios of several of these drugs.

The most common induction agents are thiopental, propofol, and ketamine, but etomidate has been used as well. All of them cross the placenta, but an effect is rarely seen in the neonate because of the first-pass effect through the fetal liver and the dilutional effects from the circulation. Thiopental is most commonly used, but propofol is gaining in popularity because of a shorter half-life and less of a residual impact. Ketamine is generally reserved for a hemorrhaging or volume-depleted patient because it is less cardiodepressive and produces a sympathetic response that better maintains the maternal hemodynamic state. Etomidate is generally reserved for patients with cardiac disease. All of these induction agents depress the maternal myocardium, but to varying degrees. As a result, intervillous blood flow initially decreases, but returns to baseline as long as maternal blood pressure is monitored and hypotension is treated.

To intubate and secure the airway in the most rapid manner possible, succinylcholine is the neuromuscular agent of choice because it has the fastest onset of action. It also has the shortest duration of action because it has a half-life of 90 seconds and is metabolized by pseudocholinesterase in the maternal plasma to benign metabolites. As a rule, no other neuromuscular blocking agent is needed during the short time from incision to delivery, so the use of succinylcholine alone would have no effect on the fetus. Sometimes succinylcholine is contraindicated or delivery is delayed, however, and a nondepolarizing neuromuscular blocking agent is required. This is a different class of neuromuscular blocker from succinylcholine, but this class of medications is hydrophilic and highly ionized. As a result, little, if any, crosses the placenta, and the fetus is not affected (see Table 25-1).

Nitrous oxide and a volatile agent such as isoflurane or sevoflurane are administered to maintain the anesthetic state. Although these agents pass to the fetus, they rarely have a direct effect, unless the time from induction to delivery is prolonged. If more than 15 minutes pass since the induction, the concentrations of these agents in the fetus equilibrate with the maternal levels, and the neonate is depressed at delivery. Ventilatory support for a few minutes is generally all that is required as these agents are expelled through the lungs. It is more important for the neonatologist to note that if the uterine incision to delivery time exceeds 180 seconds, the neonate is more likely to be depressed from a compromised perfusion and less so from these maintenance agents.[6]

ANCILLARY MEDICATIONS

Most commonly, intravenous opioids or sedatives are not administered to the mother before delivery, but occasionally it happens. Some patients demand some form of anxiolytic before cesarean section, and in those cases a small dose of midazolam (Versed) is usual. A small dose (1 to 2 mg I.V.) would not have an impact on the neonate. At other times, the neuraxial block may be inadequate for the cesarean section because either the epidural catheter is poorly positioned or insufficient time has passed for the level to increase adequately, and the anesthesia provider may administer an opioid such as fentanyl or small doses of ketamine intravenously. These medications have already been discussed, and none have a significant effect on the neonate at the dosages commonly used.

ANESTHETIC CHOICES AND MATERNAL OBSTETRIC HISTORY

Preeclampsia

Preeclampsia is a disease unique to pregnancy. Although its etiology is still unclear, it results from an imbalance of the prostaglandins produced by the placenta (see Chapter 15). The classic clinical triad in the mother is proteinuria, edema, and hypertension. The severe systemic involvement of this disease can extend from mild to life-threateningly severe, and involves multiple organ systems. One cardiovascular effect is an increase in the systemic vascular resistance. Depending on the severity of the disease, the increased systemic vascular resistance can reduce uteroplacental blood flow and compromise the fetus. As a result, it is not unusual to see a nonreassuring FHR tracing during the evaluation or induction of a patient with severe preeclampsia.

Other clinical abnormalities associated with the disease that are particularly troublesome for the anesthesia provider are edema and thrombocytopenia. A severely preeclamptic patient can develop a generalized edema that is so severe that the tissues in the airway and around the vocal cords are involved. Clinically, the patient may notice hoarseness or other change in her voice. To an attentive anesthesia provider, this manifestation signals a potential difficult airway where attempts at intubation may fail. If a general anesthetic is the only option for a surgical delivery, and the airway evaluation suggests a difficult intubation, the anesthesia provider may try to secure the airway before induction using a fiberoptic laryngoscope in an awake patient. This approach provides the advantage of airway evaluation and appropriate management. The mother would be given opioids, sedatives, and anxiolytics such as midazolam during this process, however, all of which cross the placenta. Whether intubated awake or in the usual fashion, the anesthesia provider is likely to attempt to block the sympathetic response to laryngoscopy by giving antihypertensives such as labetalol or a short-acting beta blocker such as esmolol, which can cross to the fetus. Failing to manage the hypertensive response to laryngoscopy may produce such severe increases in maternal blood pressure that an intracranial bleed may occur.

Thrombocytopenia that may occur with preeclampsia can be mild or very severe and significant enough that a regional anesthetic is contraindicated because of concerns of hematoma formation with subsequent nerve damage. The concern for the anesthesia provider has always been whether the platelets present are functional. Previously, many anesthesia providers refused to place a neuraxial block if the platelet count was less than 100,000/μL because there were no accurate tests available to determine platelet function. Although there is still no standard test to evaluate platelet function at the bedside, knowledge at present is that platelet function tends to be preserved, and so the platelet count limit of 100,000/μL is no longer valid. Most anesthesia providers place a neuraxial block at lower platelet counts, but at what lower limit a neuraxial block is contraindicated has not been determined.

Older literature reported that spinals should be avoided in preeclampsia, but it seems that spinal-induced hypotension does not occur or is muted in patients with preeclampsia. This is because the hypertension of preeclampsia is not due to sympathetic tone, but rather to the prostaglandin imbalance. Additionally, the favorable data on measured parameters seen in neonates of mothers without preeclampsia who receive a neuraxial block remain equally favorable in the neonates of mothers with preeclampsia. Some studies have also shown that in a patient with preeclampsia, intervillous blood flow improves with a regional block as long as maternal blood pressure is maintained.[17] Numerous options are acceptable for patients with preeclampsia as long as the anesthetic choice is not contraindicated by some aspect of the disease.

UTERINE RUPTURE

In response to the increased pressure to reduce the cesarean section rate in the United States during the 1990s, obstetricians began to let go of the old adage “once a section, always a section.” Women who had a low transverse uterine incision during their primary cesarean section were offered a trial of labor. If successful, the delivery was termed a *vaginal birth after cesarean* (VBAC). At first, the VBAC success rate seemed acceptable, with less overall risk than anticipated. Then a series of large studies were published and documented a scar dehiscence rate of about 1%. It had always been a concern that allowing women to attempt a vaginal birth after cesarean would result in just such a complication.

In the first few years that VBAC was promoted, obstetric providers believed that women undergoing a trial of labor should not be allowed to receive an epidural because it might mask the pain associated with a uterine rupture or scar dehiscence. Two facts reversed this attitude, however. The first was that the most common findings of either a rupture or scar dehiscence were rarely pain or even bleeding, but instead were a change in the FHR and contraction pattern. Second, with the advanced techniques in epidural analgesia, abnormal or pathologic pain during labor would “break through” the low analgesic doses of the epidural. As a result, current practice is not to deny women undergoing a trial of labor any form of epidural analgesia, but to examine them aggressively for other causes should they complain of unusual pain.

When scar dehiscence or even a true uterine rupture is recognized, an epidural that is already in place may be safely extended for a cesarean section. It is common practice, however, to proceed with a general anesthetic if nothing is in place because the fetus usually shows signs of severe distress, and the focus at this point is on delivery as fast as possible. When such an event occurs, it is more likely that the depressed neonate is suffering from the disruption in uteroplacental blood flow that occurs, and less from adverse anesthetic effects because it would be unlikely that significant amounts of medication could cross the placenta.

Fetal Distress

Fetal distress is most often a result of some level of compromise in the intrauterine environment that may be due to numerous possibilities. It generally signals a progressive process that can lead to fetal acidosis or asphyxia, and result in severe neurologic damage or death. When signs of a stressed fetus are present, the obstetric provider evaluates the clinical situation and makes the determination of whether labor remains a viable option for delivery or a cesarean section should be undertaken, and how quickly. Between the beginning of labor and that determination, a nonreassuring FHR tracing does not preclude a patient from receiving a neuraxial analgesic. As mentioned previously, the block can improve the intrauterine environment and keep the mother alert and active during obstetric management, and the negative consequences of maternal hyperventilation, catecholamine elevations, and systemic medications are avoided.

Most anesthesia providers would prefer to meet and evaluate the mother before the fetus is in such severe distress that the call for a cesarean section is an emergency, but that cannot always happen. In such a situation, many obstetricians request a general anesthetic because of the perception that a spinal takes longer to induce than a general anesthetic. Two arguments can be made against this. First, a spinal may take no longer to place than the induction of a general anesthetic, provided that it is successful on the first attempt. Second, Marx and colleagues[25] showed that even in the presence of severe fetal distress, neonatal outcomes were better in mothers who received a spinal over a general anesthetic as determined by Apgar scores and base excess values. These findings support the concept that a neuraxial block should be pursued whenever possible in the absence of hemorrhage, and underscores the need for all members of the obstetric team to communicate. There will be times, however, when the only option is to proceed with the general anesthetic.

Placenta Previa

Placenta previa is the covering of all or some portion of the cervical os by placental tissue, which may obstruct the fetal exit and places the mother at risk for hemorrhage. Previas are classified into three types that describe the varying degrees of obstruction. Complete previa covers the os completely and represents 37% of previas. This form mandates an abdominal delivery, whereas the other two types may allow for a vaginal delivery if there is no bleeding. Improved diagnostic techniques have greatly enhanced the obstetric provider's ability to diagnose and decide on a delivery method before significant hemorrhage occurs. Complete previas are generally known in advance, and an elective cesarean section under regional anesthesia is the standard. Uncontrolled bleeding is rare, and there is no increased risk to the fetus. If the decision is made to deliver the mother vaginally, and there is no evidence of hemorrhage, an epidural analgesic is an appropriate choice. The dilemma arises if the patient starts to bleed. The need to proceed to a cesarean section is obvious, but there is no correct answer regarding whether to deepen the regional block or perform a general anesthetic. The briskness of the bleeding directs much of the decision making, and the ultimate insult to the neonate.

Placental Abruption

A placental abruption is the predelivery separation of the placenta from the uterine wall. It can be complete or partial. When the abruption is incomplete and stable, the obstetric provider may prefer to observe the mother and watch for any signs of compromised blood flow to the fetus. If bleeding resumes, the separation extends, or there is fetal compromise, emergent delivery is required. Under these conditions, most anesthesia providers avoid a neuraxial block because it is difficult to determine the level of hemorrhage that is ongoing. A general anesthetic becomes the only choice. Because of the clinical situation, neonatal depression is due to the severe compromise or loss of uteroplacental flow and not to exposure to anesthetic medications.

CHAPTER 26

Delivery Room Resuscitation of the Newborn

PART 1

Overview and Initial Management

Jay P. Goldsmith

The transition from fetus to neonate represents a series of rapid and dramatic physiologic changes during which the placenta is replaced by the lungs as the primary organ of gas exchange. This transition goes smoothly most of the time; however, approximately 10% of the time the active intervention of a skilled individual or team is necessary to ensure that the newborn receives the appropriate assistance to assume independent existence as quickly as possible.[32] The need for full resuscitation, including chest compressions or medication administration or both, is relatively rare, occurring in approximately 1 to 2 per 1000 live births.[29] For these severely depressed newborns and for extremely premature infants, to avoid or minimize injury, the process of resuscitation during the first hour of life requires excellent communication, cognitive knowledge, skilled technical providers, and behaviors that are integral to a collaborative team effort.

Although certain episodes of fetal asphyxia cannot be prevented, there are many circumstances in which, in the immediate neonatal period, a prompt and skilled resuscitation may prevent death or lifelong adverse sequelae. Newborns who require medication or chest compression or both in the first few minutes after birth usually have significant fetal acidemia or inadequate ventilation after birth, or both.[29] Because the need for significant intervention cannot always be predicted, the American Heart Association (AHA) guidelines for neonatal resuscitation and the American Academy of Pediatrics (AAP) Guidelines for Perinatal Care have advised: “At least one person skilled in initiating neonatal resuscitation should be present at every delivery. An additional person capable of performing a complete resuscitation should be immediately available.”[4,6]

In the past two decades, neonatal resuscitation has been the subject of extensive research and review. The evidence evaluation process of the International Liaison Committee on Resuscitation (ILCOR) provides perhaps the most evidence-based guidelines in all of medicine.[16] Although many elements of a resuscitation sequence have been agreed on, debate and discussion regarding certain aspects of the process continue.[39] Research continues to search for answers to many questions. The guidelines published by the AAP and the AHA[6] derived from the ILCOR Consensus on Science and Treatment Recommendations[7,16] represent the best distillation of the available science at the time of their publication, however, and should serve as the foundation for any resuscitation program. Part 1 of this chapter presents guidelines for neonatal resuscitation and reviews the evolving science in this area to provide an appreciation of common and controversial questions and a basis for understanding conflicting views.

FETUS

In utero, the fetus depends on the placenta for gas exchange. Despite a PaO_2 of 20 to 30 mm Hg, a normal fetus carries on essential metabolism and is not hypoxic. The tissues receive adequate amounts of oxygen, and anaerobic metabolic pathways are not usually used. Adequate oxygen delivery is accomplished with an adaptive process primarily involving the architecture of the circulatory system, the characteristics of fetal hemoglobin, and the rate of perfusion of fetal organs.

The placenta has the lowest resistance in the circulatory system of the fetus and preferentially receives blood from the systemic circulation. Approximately 40% of the total cardiac output of the fetus flows through the placenta. Blood in the umbilical artery leaving the fetus en route back to the placenta has a PO_2 of 15 to 25 mm Hg.[22] In humans, umbilical venous blood returning from the placenta to the fetus obtained by percutaneous umbilical vein sampling has a PO_2 normally 20 to 40 mm Hg, but it may range to 45 mm Hg.[27] When the umbilical venous blood is mixed with venous return from the fetus, the resultant PO_2 is lower. Although the arterial oxygen tension of the fetus is low compared with postnatal values, the high affinity of fetal hemoglobin for oxygen shifting the oxyhemoglobin curve to the left results in only mildly diminished oxygen content of the blood.

Several adaptive and anatomic mechanisms help keep fetal tissue well perfused and oxygenated despite low oxygen tension. When the umbilical vein enters the abdomen of the fetus, the stream splits, with slightly more than half of the blood flowing through the ductus venosus into the inferior vena cava. The remaining blood perfuses portions of the liver. The umbilical venous return entering the inferior vena cava tends to stream and does not completely mix with less oxygenated blood entering the inferior vena cava from below. In the right atrium, the crista dividens splits the inferior vena cava stream so that oxygenated blood from the umbilical vein flows through the foramen ovale into the left side of the heart. The less oxygenated blood returning from the body flows into the right ventricle (Fig. 26-1).

In the fetus, blood flow through the lungs is diminished because of the high resistance of the fetal pulmonary circuit, the open ductus arteriosus, and the lower resistance of the systemic and placental circuits. Nearly 90% of the right ventricular output crosses the ductus arteriosus and enters the aorta, bypassing the lungs. With little return from the pulmonary veins, oxygen in the umbilical venous blood crossing the foramen into the left atrium is only slightly diluted. The most highly oxygenated blood perfuses the brain and heart through the carotid and coronary arteries before its oxygen concentration is decreased by blood entering the aorta through the ductus arteriosus.

Another adaptive mechanism keeping the tissues oxygenated is the rate of perfusion of fetal tissues. Fetal tissues are perfused with blood at a higher rate than in the adult. The increased delivery of blood compensates for the low oxygen saturation (SpO_2) in the fetus and the higher oxygen affinity of fetal hemoglobin. Finally, the fetus has less of an oxygen demand than the newborn. Because thermoregulation is unnecessary in the fetus, and respiratory effort is limited, two significant processes that consume oxygen in the newborn are either eliminated or markedly diminished in the fetus.

The PCO_2 of the fetus is slightly higher than adult levels: The normal umbilical venous PCO_2 is 35 to 45 mm Hg. Elimination of carbon dioxide from the fetus is enhanced by maternal hyperventilation and relative hypocarbia during pregnancy. Because of the lower PCO_2 of maternal blood, a gradient is created favoring the transfer of carbon dioxide across the placenta from fetal to maternal blood (Bohr effect).

The low fetal PO_2 contributes to the flow characteristics of the fetal circulation by helping to keep the pulmonary vascular resistance (PVR) high. The ductus arteriosus remains patent because of fetal production of prostaglandins and a relatively low PO_2.

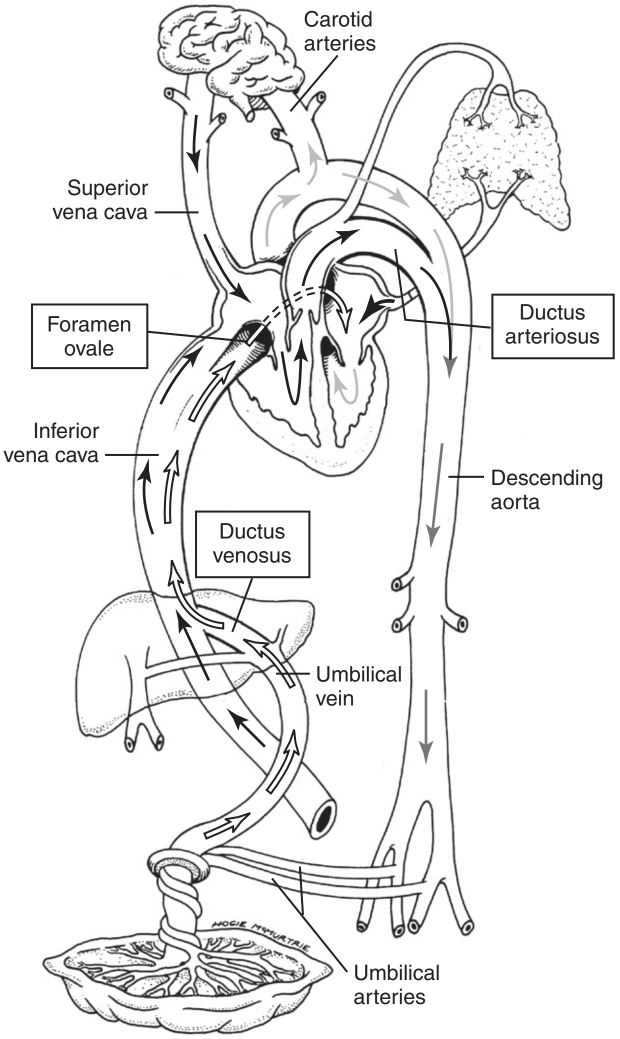

Figure 26–1. Fetal circulation.

The fetus maintains metabolic homeostasis despite low oxygen tensions because of these adaptive and anatomic characteristics. Any significant compromise of fetal gas exchange before labor (e.g., causing intrauterine growth restriction) or during the intrapartum period or lack of effective transition at birth quickly results in asphyxia, however, consisting of hypoxia, elevated PCO_2, and metabolic acidosis.

TRANSITION AT BIRTH

The circumstances and process of delivery contribute to the condition of the infant at birth. A cesarean section done before the onset of labor has a different physiologic effect on the process of transition than the standard labor process. Delivery of a multiple gestation and anesthesia administered to the mother may also be significant contributing factors. The labor process causes mild hypoxia and acidosis to some extent. With each contraction, uterine blood flow decreases, with a resulting decrease in placental perfusion and a temporary impairment of transplacental gas exchange; this is accompanied by transient hypoxia and hypercapnia. The intermittent nature of normal labor permits the fetus to "recover" between each contraction; however, the effect is cumulative. Throughout a normal labor, the fetus undergoes a progressive but slow reduction in PO_2, some increase in PCO_2, a decrease in pH, and the accumulation of a base deficit (Table 26-1).[10] In the normal circumstance, these changes are not significant enough to depress the infant and prevent normal transition from intrauterine to postnatal existence.

With birth, the neonate must establish the lungs as the site of gas exchange; the circulation, which in the fetus shunted blood away from the lungs, must now fully perfuse the pulmonary vasculature. Postnatal breathing is on a continuum with in utero breathing movements that are well established but intermittent in the term fetus. Clamping of the cord at birth stimulates peripheral and central chemoreceptors, and, in conjunction with tactile and thermal stimulation, results in an increased systemic blood pressure. This combination of events is usually enough stimulation for a noncompromised infant to pursue breathing vigorously.

The clearance of lung fluid after birth is the result of multiple processes and only minimally due to the "thoracic squeeze" during passage through the birth canal. A few days before a normal term vaginal delivery, the fetal production of lung fluid slows, and alveolar fluid volume decreases.[8] The process of labor is a powerful stimulus for the clearance of lung fluid, and that transfer of fluid from the airspaces is predominantly a process of active transport into the interstitium and drainage through the pulmonary circulation, with some fluid exiting through lymphatic drainage.[17] Although started before labor and influenced by the increasing levels of endogenous catecholamines, the process accelerates immediately after birth.

The first few breaths must facilitate clearance of fluid from the lungs and establish a functional residual capacity (FRC).[36,37,41] (See also Part 2 of this chapter.) The first breath of a spontaneously breathing infant has some unique characteristics. Although the peak inspiratory pressure is usually between -20 cm H_2O and -40 cm H_2O, the opening pressures are very low. That is, gas begins to enter the lungs at very low pressures, usually less than -5 cm H_2O pressure. Very high expiratory pressures are also generated, pressures that generally exceed the inspiratory pressure. This expiratory pressure, probably generated against a closed glottis, aids in clearing lung fluid and leads to a more even distribution of air throughout the lung. In a vigorous, spontaneously breathing, vaginally delivered infant, a significant FRC develops at the end of the first breath (Fig. 26-2).[24]

Expansion of the lungs is a stimulus for surfactant release, which reduces alveolar surface tension, increases compliance, and helps maintain a stable FRC. Simultaneously, the act of ventilation alone reduces PVR. Ventilation leads to a decrease in PCO_2 and an increase in pH and PO_2, also causing a decrease in PVR.[11] In a study of lambs, Lakshminrusimha and colleagues[19] showed that PVR decreased nearly as much (72%) in the first 30 minutes after birth with air resuscitation as with 100% oxygen. By 60 to 90 minutes after birth, the decrease in PVR in the air group had reached the same level as the 100% oxygen group. Figure 26-3 illustrates the relationships between pH, PO_2, and PVR.[28] Clearance of lung fluid, establishment of FRC, and a decrease in PVR with an increase in pulmonary blood flow facilitate ventilation and oxygenation.

With the onset of ventilation, the fetal circulatory system assumes the adult pattern. Coincident with clamping of the cord, the low-resistance placenta is removed from the systemic circuit, and systemic blood pressure increases. This increase in systemic pressure, coupled with the decrease in PVR and in pulmonary artery pressure, decreases the right-to-left shunt through the ductus arteriosus. The increase in PaO_2 further stimulates functional closure of the ductus arteriosus. With ductal shunting diminished, pulmonary artery blood flow increases, resulting in increased pulmonary venous return to the left atrium and increased pressure in the left atrium. When the left atrial pressure exceeds right atrial pressure, the foramen ovale functionally closes.

An uncomplicated transition from fetal to newborn status is characterized by loss of fetal lung fluid, secretion of surfactant, establishment of FRC, decrease in PVR, increased

TABLE 26–1 Fetal Scalp Blood Values during Labor*

	Early First Stage	Late First Stage	Second Stage
pH	7.33 ± 0.03	7.32 ± 0.02	7.29 ± 0.04
PCO_2 (mm Hg)	44 ± 4.05	42 ± 5.1	46.3 ± 4.2
PO_2 (mm Hg)	21.8 ± 2.6	21.3 ± 2.1	16.5 ± 1.4
Bicarbonate (mmol/L)	20.1 ± 1.2	19.1 ± 2.1	17 ± 2

systemic pressure after removal of the low-resistance placenta from the systemic circuit, functional closure of two shunts (ductus arteriosus and foramen ovale), and increase in pulmonary artery blood flow. In most circumstances, the mild degree of asphyxia associated with labor is insufficient to interfere with this process. Regardless of the mode of birth, the transition may be significantly altered by various antepartum or intrapartum events, resulting in cardiorespiratory depression, asphyxia, or both. Infants who are very premature are especially vulnerable to these untoward events.

CAUSES OF DEPRESSION AND ASPHYXIA

A newborn may be compromised because of problems initiated in utero with the mother, the placenta, or the fetus itself (Box 26-1). A process initiated in utero may extend into the neonatal period, preventing a normal transition. An asphyxial process also may be neonatal in origin—that is, the infant seems well until required to breathe on his or her own.

BOX 26–1 **Factors Associated with Neonatal Depression and Asphyxia**

ANTEPARTUM RISK FACTORS

- Maternal diabetes
- Pregnancy-induced hypertension
- Chronic hypertension
- Chronic maternal illness
  - Cardiovascular
  - Thyroid
  - Neurologic
  - Pulmonary
  - Renal
- Anemia or isoimmunization
- Previous fetal or neonatal death
- Bleeding in second or third trimester
- Maternal infection
- Polyhydramnios
- Oligohydramnios
- Premature rupture of membranes
- Post-term gestation
- Multiple gestation
- Size-dates discrepancy
- Drug therapy
  - Lithium carbonate
  - Magnesium
  - Adrenergic blocking drugs
  - Selective serotonin reuptake inhibitor antidepressants
- Maternal substance abuse
- Fetal malformation
- Diminished fetal activity
- No prenatal care
- Age <16 or >35 years

INTRAPARTUM RISK FACTORS

- Emergency cesarean section
- Forceps or vacuum-assisted delivery
- Breech or other abnormal presentation
- Premature labor
- Precipitous labor
- Chorioamnionitis
- Prolonged rupture of membranes (>18 hours before delivery)
- Prolonged labor (>24 hours)
- Prolonged second stage of labor (>3 hours)
- Fetal bradycardia
- Nonreassuring fetal heart rate patterns
- Use of general anesthesia
- Uterine tetany
- Narcotics given to mother within 4 hours of delivery
- Meconium-stained amniotic fluid
- Prolapsed cord
- Abruptio placentae
- Placenta previa

Maternal causes of fetal compromise may be related to decreased uterine blood flow, which decreases the amount of oxygen transported to the placenta. Diminished uterine blood flow may result from maternal hypotension (as a result of drugs used to treat hypertension), regional anesthesia, eclampsia, or abnormal uterine contractions. Problems with the placenta, such as infarcts, premature separation, edema, or inflammatory changes, may impair gas exchange. The fetus also may be compromised because of fetal problems related to cord compression, such as nuchal cord, prolapse, or a breech presentation with cord compression by the aftercoming head, or by intrinsic fetal problems such as anemia or congenital abnormalities. In some cases, inflation of the lung occurs normally, but there may be a deficiency in oxygen carrying capacity, as in severe hypovolemia from acute hemorrhage or fetomaternal transfusion, or there may be inadequate cardiac output from numerous causes. A neonate may not breathe after delivery because of many problems, including asphyxia, drug-induced central nervous system (CNS) depression, CNS anomalies or injury, spinal cord injury, mechanical obstruction of the airways, deformities, immaturity, pneumonia, or congenital anomalies.

Finally, there are some circumstances in which the infant may initiate breathing only to diminish markedly or stop breathing soon after birth. Examples include extreme prematurity with inadequate ventilatory support after birth, drug-induced depression in which the stimuli surrounding birth initially overcome the depression, congenital diaphragmatic hernia (CDH), and spontaneous pneumothorax.

RESPONSE TO ASPHYXIA

The goal with any depressed or asphyxiated infant, whether the process is initiated in the fetal or the neonatal period, is to reverse the ongoing events as soon as possible and avoid death or permanent injury. An understanding of the response of the fetus or neonate to asphyxia forms the basis of the resuscitative process.

Intrapartum asphyxia can be divided into two major types: acute near-total asphyxia and partial prolonged asphyxia. Acute near-total asphyxia has an abrupt onset, usually lasts 5 to 30 minutes, and causes complete or near-complete cessation of blood flow to the fetus. Etiologies include uterine rupture, complete placental abruption, and severe cord compression. Partial prolonged asphyxia occurs more slowly over many hours and usually results from various causes of uteroplacental insufficiency. When a fetus or neonate is subjected to partial prolonged asphyxia, the classic "diving" reflex occurs; this is simply an attempt either to accentuate or to restore a fetal type of circulation. Hypoxia and acidosis, regardless of their duration, increase vasoconstriction of the pulmonary vasculature (see Fig. 26-3).[31] The increase in PVR results in a decline in pulmonary blood flow, decreasing left atrial return, which lowers left atrial pressure. The decline in left atrial pressure increases right-to-left shunting across the foramen ovale. In the fetus, this shunting directs the most highly oxygenated blood coming from the placenta to the left side of the heart. In a neonate with no placenta, this shunting merely bypasses the lungs, perpetuating a vicious cycle of hypoxia, more acidosis, and more shunting. In acute near-total asphyxia, there may not be time for the diving reflex to have a physiologic effect; in contrast to partial prolonged asphyxia, there may not be significant multisystem organ damage from shunting of blood away from the kidneys, liver, bones, and other nonvital organs.

In the fetus and the neonate, the increase in noncerebral peripheral resistance during prolonged asphyxia results in a redistribution of blood flow, with increased flow to the head, heart, and adrenals, and decreased flow to nonvital organs. Although the oxygen content of the blood is low, during the early stages of asphyxia the amount of oxygen brought to the head and heart is maximized by the maintenance of cardiac output and the increased flow to these organs.[25] The increased peripheral resistance increases blood pressure early in asphyxia. The blood pressure remains at reasonable levels as long as the myocardium is able to sustain cardiac output. As the asphyxia progresses, and hypoxia and acidosis worsen, the myocardium fails, and cardiac output and blood pressure decrease.[14]

Hypoxic cardiomyopathy is the intermediary to significant brain and other organ damage in partial prolonged asphyxia. In most cases, infants are born with a heart rate, although it may be less than 100 beats/min. The resuscitation algorithm of children and adults emphasizes interventions to promote the return of spontaneous circulation and does not apply in newborns; the provision of adequate ventilation is the mainstay of neonatal resuscitation with the goals to reverse the bradycardia and restore adequate circulation. Superimposed on these circulatory and hemodynamic changes is a characteristic change in respiratory pattern. Initially, there are gasping respirations (which may occur in utero). With continuing asphyxia, respirations cease in what is known as primary apnea. If the asphyxia is not corrected, the infant again begins to gasp irregularly, and the respirations cease (secondary apnea), unless positive pressure ventilation (PPV) and successful resuscitation occur (Fig. 26-4).[13]

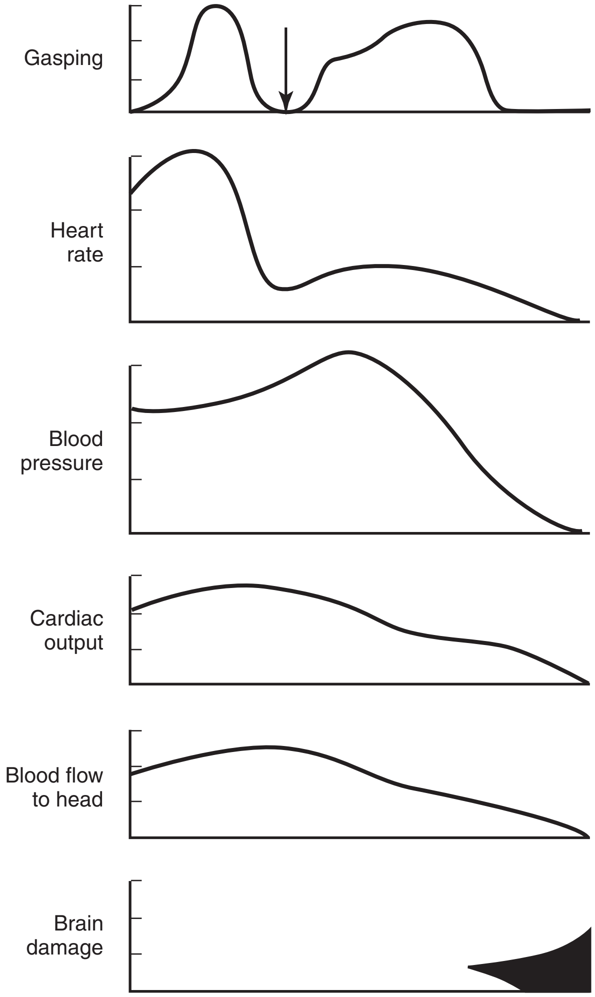

Figure 26–4. Schematic diagram of changes associated with asphyxia. Arrow indicates point of primary apnea. *(Modified from Dawes GS:* Fetal and neonatal physiology, *Chicago, 1968, Year Book Medical, p 149; and Phibbs RH: Delivery room management of the newborn. In Avery G, editor:* Neonatology, *3rd ed, Philadelphia, 1987, Lippincott, p 215.)*

Primary apnea usually responds to the cessation of the asphyxiating insult and stimulation. Secondary apnea is usually accompanied by severe metabolic acidemia and requires much more vigorous resuscitation for the newborn to recover. The longer the asphyxia has gone on, the longer it takes for the onset of spontaneous ventilation to occur after PPV is started (Fig. 26-5).[1] Asphyxia may begin before birth, and the infant may pass through any or all of these stages of the asphyxial response in utero. It may be difficult to determine at birth how far the asphyxial episode has progressed. With any depressed infant, it is essential to assume that the infant is in secondary apnea, and resuscitation should be initiated without delay. The goal of resuscitation, although not always attainable, is to initiate interventions in a timely and effective manner so that the insults of hypoxia, ischemia, and acidosis are reversed before they cause permanent injury (Box 26-2).

PREPARATION FOR RESUSCITATION

The key elements in preparing for resuscitation are anticipation of the problem, provision of adequate equipment, and presence of trained personnel. The chaos that sometimes occurs with resuscitation of an infant, especially an unexpected resuscitation, is primarily caused by either inadequate or unavailable equipment, or staff members who are unskilled or have difficulty coordinating their activities. In most cases, appropriate preparation can ameliorate many of these problems. The training of personnel using simulation has been shown to be an effective preparation for the teamwork and communication needed in the emergent situation of a neonatal resuscitation.[38] Training should include cognitive learning and technical and behavioral skills to conduct a resuscitation appropriately. Until more recently, the provision of adequate models to practice technical skills (e.g., intubation, catheter placement) has been a major impediment in the training of personnel for the rare full resuscitation. New high-fidelity manikins now available provide much greater realism and anatomic fidelity to solve this problem in training.[26]

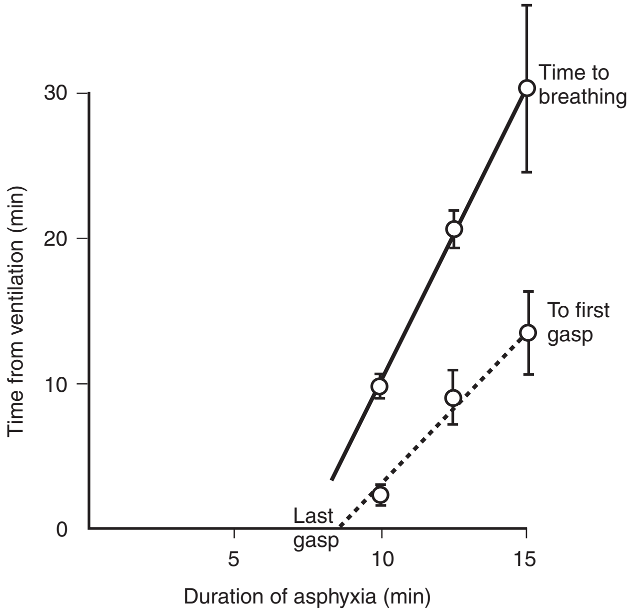

Figure 26–5. Time from ventilation to first gasp and to rhythmic breathing in newborn monkeys asphyxiated for 10, 12.5, and 15 minutes at 30°C. (*From Adamsons K et al: Resuscitation by positive pressure ventilation and tris-hydroxymethylaminomethane of rhesus monkeys asphyxiated at birth,* J Pediatr *65:807, 1964.)*

BOX 26–2 Consequences of Asphyxia

CENTRAL NERVOUS SYSTEM
- Cerebral hemorrhage
- Cerebral edema
- Hypoxic-ischemic encephalopathy
  - Seizures
  - Stroke

LUNG
- Delayed onset of respiration
- Acquired surfactant deficiency (respiratory distress syndrome)
- Meconium aspiration syndrome

CARDIOVASCULAR SYSTEM
- Myocardial failure
- Papillary muscle necrosis
- Persistent pulmonary hypertension of the newborn

RENAL SYSTEM
- Cortical/tubular/medullary necrosis

GASTROINTESTINAL TRACT
- Necrotizing enterocolitis

BLOOD
- Disseminated intravascular coagulation

Anticipation

Communication between the obstetric and neonatal teams is essential to the graded response needed for neonatal resuscitation. In some situations, a single competent person is appropriate to the clinical situation. At other times, a full resuscitation team of three or more skilled providers is necessary. A careful review of the antepartum and intrapartum history can identify many problems that put a mother at risk of delivering a depressed or asphyxiated infant (see Box 26-1) and determine the composition of the resuscitation team. Even an emergency call for assistance to the neonatal team should include all pertinent information; the acronym *HANDS* may be helpful to highlight the most important data: *H* for hemorrhage, *A* for amniotic fluid (meconium-stained), *N* for number of infants expected, *D* for dates (gestational age), and *S* for fetal monitoring strip.

Identifying a high-risk situation before delivery of the infant provides time for adequate preparation and gathering the appropriate personnel in the delivery room. Because of modern obstetric techniques and anesthesia, it is no longer necessary to consider a repeat cesarean section as a high-risk delivery because this form of delivery carries no greater risk than a vertex vaginal delivery.[20] Only if the cesarean section involves fetal distress or other complications is there any cause for added concern. It is impossible to identify every infant who may need assistance. At every delivery, equipment and personnel should be available in case of unanticipated depression.

Adequate Equipment

Whenever an infant is delivered, appropriate equipment must be close at hand and in good working order. An area in or near the delivery room should be designated as the resuscitation area, and provisions should be made for adequate space, heat (radiant warmer), blended oxygen, and suction. Supplies and drugs as specified in the resuscitation guidelines should be placed in a code cart or bag or attached to a wall board for easy access. These supplies should be routinely checked by hospital personnel and rechecked for completeness and good working order (e.g., laryngoscope light works) before an anticipated resuscitation. A delay in effective resuscitation may occur if someone needs to leave the delivery room during the procedure to obtain an essential piece of equipment.

Adequate Personnel

Individuals vested with the responsibility of resuscitating infants should be adequately trained, readily available, and capable of working together as a team. Having trained personnel readily available means having someone present at every delivery who has the skill required to perform a complete resuscitation, with other available staff close at hand in case they are needed. This person does not have to be a physician, but should be able to perform the technical skills and have the cognitive knowledge necessary. The hospital is responsible to ensure the competence of these personnel in the same way a surgeon is credentialed to perform certain operations.[4] At least two, if not three, people are needed to carry out a full resuscitation. Adequate training involves more than simply going through a course and receiving a certificate of completion. The neonatal resuscitation program of the AHA/AAP and similar courses are simply starting points.[6] They do not ensure competence or qualify one to assume independent responsibility.

Finally, the personnel available to the delivery room should be capable of working together as a team. If staff are skilled at carrying out their responsibilities and can anticipate each other's needs, the tension inherent in any resuscitation can be reduced, and the process will go much more smoothly. Simulation training using manikins and holding mock code drills on an ongoing basis helps to maintain skills and develop coordination among staff.[26]

APGAR SCORE

The Apgar score is a tool that can be used objectively to define the state of an infant at given times after birth, traditionally at 1 minute and 5 minutes (Table 26-2).[3,5] The Apgar score should not be used as the primary indicator for resuscitation because it is not normally assigned until 1 minute of age. As noted earlier, asphyxia may begin in utero and continue into the neonatal period. To minimize the chances of brain damage, one should begin resuscitation as soon as there is evidence that the infant is unable to establish ventilation sufficient to maintain an adequate heart rate. Waiting until a 1-minute Apgar score is assigned before initiating resuscitation only delays the initiation of the resuscitation. An Apgar score at 1 minute of 0 to 3 often indicates the presence of secondary apnea. Infants who fail to achieve an Apgar score of 7 by 5 minutes of age should have repeated Apgar scores every 5 minutes until the score is at least 7.[5] Resuscitation-assisted Apgar scores should be appropriately documented in the medical record.[5]

ELEMENTS OF A RESUSCITATION

A resuscitation can be viewed as a series of elements (Box 26-3). The process is not a linear set of steps in which one marches inexorably from one point to another. Rather, it involves an evaluation of the infant's condition, a decision based on that evaluation, and action. These steps are repeated until the process is concluded. Figure 26-6 provides an overview of the resuscitation process.[6]

Virtually all infants undergo the initial steps. Most infants requiring active resuscitation respond to PPV.[29] All infants, whether they require only the initial steps or a complete resuscitation, are entitled to a skilled and timely response, regardless of who is performing the resuscitation. Parents may be present while perinatal care is being provided to neonates, including procedures, resuscitation, and stabilization. Parents should be informed about and involved in the care of their infants within the principles of family-centered care.[15]

Initial Quick Overview

Most infants are vigorous, cry at birth, and breathe easily thereafter. Many times, delivery room staff and the parents prefer that the infant go to the mother immediately after birth, rather than be placed on a warmer and put through the "initial steps" in resuscitation. In most circumstances, a

TABLE 26–2 Apgar Score

Sign	0	1	2
Heart rate	Absent	<100 beats/min	>100 beats/min
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Vigorous cry

- Chest compression
- Medication

healthy and vigorous infant does not even require suctioning after delivery. With appropriate triaging and oversight, many, if not most, infants can be given directly to the mother after birth without compromising the infant.

A rapid initial assessment that provides the information necessary to triage the infant appropriately is required. If the infant has not passed meconium in utero, is term, is breathing easily, has good tone, and appears normal and vigorous, it may be appropriate to hand the child to the mother immediately after birth. As the mother holds the infant, a light blanket may be provided to prevent rapid evaporative heat loss while covering the infant in such a way as to be able to observe the infant for signs of increasing distress. If the infant has passed meconium in utero, is preterm, is not breathing easily, has diminished tone, or does not appear normal and vigorous, the infant should be placed on a radiant warmer until a more thorough assessment of the infant can be done.

The following steps apply to any infant who is not term, healthy, and vigorous at birth. Evaluation of color at birth is usually not helpful in determining the status of a newborn because it may take several minutes for even a healthy term infant to achieve $\text{Sp}O_2$ greater than 90% and "become pink."[33] (See "Oxygen Therapy" later on.)

Initial Steps

THERMAL MANAGEMENT

Delivery rooms are kept at a level of thermal comfort for the adults working in them. The neonate, with a very large surface area-to-mass ratio, is susceptible to cold stress; this is especially true for infants with extremely low birthweight. Studies have shown that 30% of infants with extremely low birthweight (<1000 g), become hypothermic with standard warming techniques in the delivery room.[21,40] Because this population makes up less than 1% of all deliveries, special preparations should be made by prewarming the delivery room to 75°F to 78°F and using a food-grade plastic wrap to keep the infant warm after birth.[21,40] For a term newborn, the

infant should be placed skin-to-skin with the mother or in the microenvironment of a preheated radiant warmer immediately after birth. The infant should be thoroughly dried, and the wet blankets should be promptly removed to avoid evaporative heat loss. These simple measures can minimize the decrease in core temperature that the term infant experiences at birth.[23] Preventing excessive heat loss can become especially important with a preterm infant or an infant who is asphyxiated and hypoxic. Because hypoxia blunts the normal response to cold, a hypoxic infant undergoes a greater than normal decline in core temperature if not thermally protected.[9] Recovery from acidosis also is delayed by hypothermia.[2] (See also Chapter 30.)

CLEARING THE AIRWAY

Normally, the airway is cleared with the use of a bulb syringe or a suction catheter. The mouth is suctioned first in case the infant gasps when the nose is suctioned. Care should be exercised to suction the infant gently because vigorous suctioning and stimulation of the posterior portion of the pharynx may induce bradycardia.[12] If a suction catheter is to be used, it is recommended that in the term infant the catheter be inserted no more than 5 cm from the lips, and that the duration of suctioning be no more than 5 seconds.[18] An infant exposed to meconium in the amniotic fluid represents a special circumstance (discussed later).

TACTILE STIMULATION

Usually, the act of drying and suctioning the infant is enough tactile stimulation to initiate respiration. If the infant does not breathe after these efforts, flicking the soles of the feet or rubbing the infant's back may be enough additional stimulation to elicit regular respirations. If there is no immediate response to this additional stimulation, PPV should be quickly initiated. Continued tactile stimulation is not useful and may be harmful because the asphyxia would be permitted to persist that much longer. The decisions from this point revolve around the response of the infant—primarily heart rate and respirations.

FREE-FLOW OXYGEN

Over the past several years, there has been considerable discussion and research on the use of oxygen in neonatal resuscitation.[30,34,35] (See Part 3.) Previously, the Neonatal Resuscitation Guidelines recommended free flow oxygen to be used if the newborn remained cyanotic after 30 seconds of initial steps (drying, warmth) and evaluation, or if PPV was needed. If chest compressions or medication or both were needed, 100% oxygen was recommended (see Fig. 26-6).[6] More recently, research has advised against the routine use of oxygen for transient cyanosis and the avoidance of high concentrations of oxygen whenever possible.[34,35]

If the infant is spontaneously breathing, and the heart rate is greater than 100 beats/min, but the infant remains cyanotic for 2 or 3 minutes after birth, oxygen may be administered through a free-flow system until it can be shown that the oxygen concentration can be reduced (arterial oxygen saturation [SaO_2] >85%) or that lowering the concentration makes no difference (cyanotic heart disease). More recent studies of normal term newborns have shown, however, that it may take 6 minutes or longer for infants to reach SaO_2 greater than 90%, and many clinicians believe the use of oxygen should be restricted in this situation.[33] A high concentration of oxygen can be obtained with an oxygen mask (with escape holes) held firmly over the face or an oxygen tube cupped in the hand. A flow-inflating bag (but not a self-inflating bag) is capable of delivering high concentrations of blow-by oxygen.[6] The use of high concentrations of oxygen is not usually necessary, and hyperoxia should be avoided, especially in a preterm infant.

It is best to heat and humidify the oxygen. During an emergency, cold, dry oxygen can be given; however, if free-flow oxygen is to be continued for any period, it should be heated and humidified and given through wide-bore tubing. An oxygen blender and oximeter are useful in determining the amount of oxygen the infant requires. It is recommended that hospitals that routinely deliver infants less than 32 weeks' gestation should be capable of blending oxygen in the delivery room and using pulse oximetry in this area.[6] After suctioning and tactile stimulation, if the respirations are gasping or are insufficient to sustain the heart rate at greater than 100 beats/min, PPV must be initiated.

PART 2

Role of Positive Pressure Ventilation in Neonatal Resuscitation

Arjan B. te Pas and Colin J. Morley

A newborn undergoes important physiologic adaptations in the first few minutes after birth. The first breaths after birth are characterized by a transition from liquid-filled to air-filled lungs, release of surfactant, creation of lung volume with air (FRC), increase in pulmonary blood flow, and establishment of regular respiration. Uniform aeration of the lung and establishment of appropriate FRC are required to facilitate effective gas exchange and improve oxygenation, which improves the heart rate. If an infant does not achieve this transition promptly and effectively, intervention from the caregiver is required.

Resuscitation of infants at birth is almost always a matter of establishing effective ventilation.[37] Chest compressions and medication are very rarely needed during resuscitation and are often secondary to severe acidemia or improper ventilation or both.[37] In the last decade, caregivers for neonates have been guided by evidence-based resuscitation guidelines created by ILCOR.[22] Although these guidelines are useful,[22] the evidence for the efficacy and relative merits of various approaches to initial respiratory support for infants is limited and reflects the difficulties with conducting clinical studies in the delivery room. Current recommendations for ventilation are based on relatively few clinical studies and are mostly extrapolated from small case studies, studies performed in asphyxiated or immature animals, and in vitro tests.[47]

In the ILCOR guidelines, although some distinction is made between the ventilatory approach of term and preterm infants at birth, evidence for these recommendations is also meager.[22] At birth, the lungs of preterm infants are most vulnerable, and injury can occur with the first manual inflations.[43]

Current research is challenging widely held views about neonatal “resuscitation,” and suggesting that a less aggressive, more gentle approach may be more beneficial and cause less lung injury. Part 2 of this chapter reviews the supporting evidence for current recommendations and alternative approaches.

LESSONS FROM THE FIRST BREATHS OF LIFE

Until the infant takes his or her first breath, the lung is filled with liquid. An “opening pressure” is required to overcome the frictional resistance of liquid movement through the airways and the lung recoil associated with a newly formed surface tension, and to drive the air-liquid interface into the distal airways to aerate the lung. Vyas and coworkers[55] recorded that during the first breaths, term infants can generate very high inspiratory pressures (mean 52 cm H_2O, range 28 to 105 cm H_2O) and positive expiratory pressures (mean 71 cm H_2O, range 18 to 115 cm H_2O) to achieve an average inspired volume of 40 mL. At the end of inspiration, there is a positive intrathoracic pressure, but no loss of gas from the lungs because of a closed glottis. This pressure probably facilitates the distribution of air within the lung and promotes liquid clearance. Imaging of the lung with phase contrast x-rays showed that the spontaneous entry of air into the lung depends on the generation of a transpulmonary pressure created by inspiratory efforts, promoting the movement of liquid into the interstitial tissue compartment from which it was gradually cleared.[18]

Measurements of respiratory activity in healthy term infants at birth indicate that the first breaths tend to be deeper and longer than subsequent breaths, and are characterized by a short deep inspiration followed by a prolonged expiratory phase through a (partially) closed larynx.[24] This interruption or hold of expiratory flow is known as *expiratory braking* and can result in high positive airway pressure when closure of the larynx is accompanied by abdominal muscle contraction, pressurizing the gas in the lungs. The first breaths of preterm infants are also characterized by expiratory braking, and very preterm infants treated with continuous positive airway pressure (CPAP) frequently slow and lengthen the time for expiration (Fig. 26-7).[49] Crying in term and preterm infants immediately after birth also uses expiratory braking and facilitates lung volume recruitment (Fig. 26-8).[51]

The gas flow patterns of spontaneously breathing infants immediately after birth[49,51] are completely different from the patterns when manual inflations are given during neonatal resuscitation. During manual inflations with a self-inflating bag, a positive expiratory pressure is not used. The effectiveness of respiratory support in the delivery room may be improved by using a strategy of aeration similar to spontaneous expiratory braking and breath holding. The increase in intrathoracic pressure during expiration through a narrow glottis in spontaneous breathing could be mimicked by applying positive end-expiratory pressure (PEEP) during manual ventilation or supporting spontaneous breathing with CPAP. The effect of the infant’s expiratory hold could be mimicked by giving a sustained inflation with the first inflation.

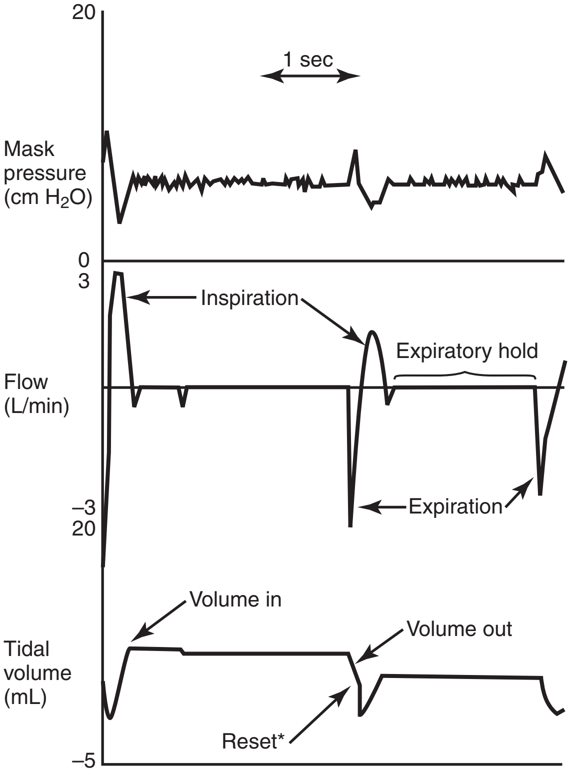

Figure 26–7. Expiratory braking by a preterm infant treated with continuous positive airway pressure just after birth. The two breaths show the expiratory hold pattern, or laryngeal braking. There is a short, large inspiration followed by a period of no expiratory flow ending with a single, very short expiratory flow peak. In some breaths (not shown here), there may be multiple expiratory flow peaks as the larynx opens and closes. Expiration is immediately followed by an inspiration; there is no postexpiratory pause. *The software resets the tidal volume to 0 at end expiration. *(From te Pas AB et al: Spontaneous breathing patterns of very preterm infants treated with continuous positive airway pressure at birth,* Pediatr Res *64:281, 2008.)*

WHEN TO INITIATE POSITIVE PRESSURE VENTILATION

According to the 2005 ILCOR guidelines, PPV should be started if the infant is apneic, has irregular or gasping respirations or a heart rate less than 100 beats/min, or is cyanotic despite being given 100% oxygen. With these recommendations, the following should be taken into consideration, however, when making the decision about starting ventilation:

1. It may take about 30 seconds before an infant takes his or her first breath.[24,55]
2. It is likely that in an irregularly breathing infant, manual inflations would be asynchronous with the spontaneous breaths. This nonsynchronized ventilation may lead to inadvertent high pressures and increases the risk for injury, such as pneumothoraces.[14]

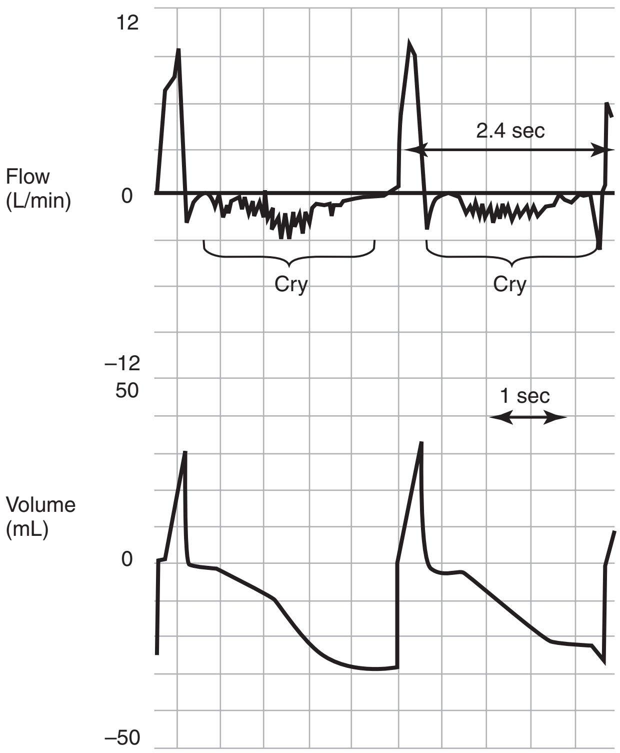

Figure 26–8. Example of crying immediately after birth in a term infant. This is characterized by a large inspiration followed by high frequency interruptions to the expiratory flow wave, which can be seen in the wave as a noise signal. Expiration is then immediately followed by inspiration. A cry has a higher amplitude and frequency than a grunt. The software resets the volume trace at the end of inspiration and end of expiration as soon as the flow reaches baseline. *(From te Pas AB et al: Breathing patterns in preterm and term infants immediately after birth,* Pediatr Res *65:352, 2009.)*

3. The delivered tidal volume, when using a set inflating pressure, depends on the compliance of the lung and the spontaneous respiratory effort of the infant.
4. To avoid these problems, an alternative approach is to support the insufficient, but spontaneous breathing with CPAP.
5. Observing whether a newborn is cyanotic is subjective and unreliable.[34] Accurate readings of SpO_2 can be obtained from the right hand or wrist by about 1 minute after birth.[23]
6. SpO_2 is about 60% in utero and can decrease to 30% during labor and delivery.[10] Immediately at birth, SpO_2 of a term infant increases from about 60% at 1 minute to 90% at 10 minutes; the lower end of the normal range at 5 minutes is about 70%.[23]
7. The key sign of an infant's condition in the minutes after birth, and response during stabilization, is the heart rate. Auscultation of the heart rate or palpation of the pulse may not be accurate when ascertained intermittently. A continuous, accurate measure of the heart rate can be obtained by pulse oximetry.
8. Bradycardia is quite common in the first 2 minutes after birth. The bradycardia can be due to hypoxia, a vagal reflex, or circulatory changes after the cord is cut and while the heart is adapting. An infant who has good tone is unlikely to be severely hypoxic at birth.

REDUCING LUNG INJURY DURING MANUAL VENTILATION

Neonatologists are familiar with the lung injury induced by PPV, caused by overdistention of the lung (volutrauma) and repeated alveolar collapse and reexpansion (atelectrauma).[2] Animal studies have shown that this can happen with the first manual inflations after birth and can trigger an inflammatory process.[43] Administration of prophylactic surfactant provides incomplete protection against the adverse effects of large lung inflations at birth in immature lambs.[21] Hillman and colleagues[16] also showed that an injurious process in the lung and an acute-phase response was initiated when preterm lambs were ventilated after birth for 15 minutes with a tidal volume of 15 mL/kg and no PEEP.

The results of these experimental studies advocate that to reduce lung injury during the first few minutes of life, existing knowledge about the causes and prevention of lung injury during ventilation should be applied from birth in preterm infants instead of waiting until the infant has been admitted to the neonatal intensive care unit (NICU).[43] Actions related to prevention of lung injury include avoiding large tidal volumes, facilitating and maintaining FRC, and avoiding repeated lung expansion and collapse.

POSITIVE PRESSURE VENTILATION

Peak Inflation Pressures and Tidal Volumes

On the basis of a few data, it is advised to use a peak inflation pressure (PIP) of 30 to 40 cm H_2O for term infants to aerate the lung at birth.[54,56] These pressures were shown to result in mean inflation volumes of about 5 mL/kg, half of the volume measured in spontaneously breathing term newborns.[3] Upton and Milner[54] resuscitated asphyxiated infants via an endotracheal tube and found that a median mean pressure of 40 cm H_2O (range 28 to 60 cm H_2O) over the first 10 breaths was needed to elicit chest rise. Two thirds were preterm infants (median gestational age 33 weeks), but half failed to establish any FRC.

There are two problems with using a fixed inflating pressure for all infants during resuscitation: (1) The tidal volume delivered is strongly influenced by the compliance of the lung, which varies among infants and changes as the lung aerates. (2) The tidal volume varies considerably depending on whether the infant is completely apneic or inspiring during inflation.

The pressure needed to resuscitate very preterm infants is even more controversial. Resuscitation guidelines, based on expert consensus but little evidence, recommend 20 to 25 cm H_2O for initial PIP in preterm infants because the lungs of sick preterm infants may have a lower compliance. Higher PIPs may be needed, however, if the infants are apneic.[22] Nonetheless, Hoskyns and associates[19] reported that endotracheal resuscitation of preterm infants with inflation pressures of 25 to 30 cm H_2O rarely lead to tidal volumes of more than 4 mL/kg, and higher pressures were sometimes needed for optimal resuscitation. In contrast, Hird and colleagues[17] found a median inflation pressure of 22.8 cm H_2O was necessary to achieve observable chest rise in preterm infants, and no infant required a PIP greater than 30 cm H_2O. It was unclear, however, whether they were breathing or not.

It is impossible to give any detailed advice about what PIP is needed for any individual infant to produce an appropriate tidal volume and FRC because it depends on various factors, including (1) the spontaneous breathing activity of the infant; (2) the lung compliance and resistance, which change as the lungs aerate; (3) the amount of lung liquid, and how quickly it is absorbed; and (4) the inflation time used. "Adequate chest rise" has been used as a criterion for appropriate ventilation in clinical studies.[17,54] This is a very subjective measure of lung expansion, however; it is often inaccurate and may lead to delivery of either inadequate or excessive tidal volumes.[28]

The inflation pressure is a very crude substitute for the tidal volume. Immediately after birth, it is impossible to deliver an appropriate tidal volume by using a set pressure because the conditions vary from infant to infant and during the course of each resuscitation. Clinicians should be aware of the tidal volume used during PPV and attempt to deliver less than 8 mL/kg, particularly with very preterm infants.[46] Tidal volumes normally targeted in the NICU (4 to 5 mL/kg), with a ventilation rate of about 60/min, may represent a good starting point.[25] To aerate the lung after birth, one can opt for higher PIPs during the first manual inflations or prolong the inspiratory time and deliver a sustained inflation to overcome the high initial resistance of a liquid-filled lung.

Prolonged Initial Inflation

The long time constant of a liquid-filled lung and the observation of spontaneously prolonged initial breaths at birth[24] encouraged Vyas and coworkers[56] to use a sustained initial inflation in apneic infants (Fig. 26-9). The tidal volumes measured were similar to the tidal volumes measured during spontaneous first breaths (see Fig. 26-9).[56] The use of a sustained inflation during resuscitation has since been studied in preterm infants, with conflicting results.[15,26,27] Many clinicians do not use a sustained inflation because they are concerned about volutrauma if large volumes enter the lung. This concern seems paradoxical considering the general acceptance of recruitment maneuvers during high frequency ventilation in the NICU when lungs have a short time constant.[7] Without the early formation of FRC, ventilation is from a low lung volume, and atelectrauma is likely.

In addition, during the spontaneous prolonged first breaths, large inspired tidal volumes have been measured.[24] It has been shown in a preterm rabbit model, using phase contrast imaging and plethysmography, that applying a sustained inflation of 20 seconds leads to a large first inspiratory volume, but does not cause overexpansion of the lung because the gas volumes achieved were not different from the volumes achieved at end expiration during ventilation with PEEP and a tidal volume of approximately 10 mL/kg.[52] It also has been shown that a sustained inflation immediately leads to appropriate FRC and more uniformly aerated lung.[52] As a result, the whole lung is available for tidal ventilation from the start, and gas exchange is likely to be more efficient. The time constant of the lung varies among individuals, and also is determined by the initial pressure gradient.

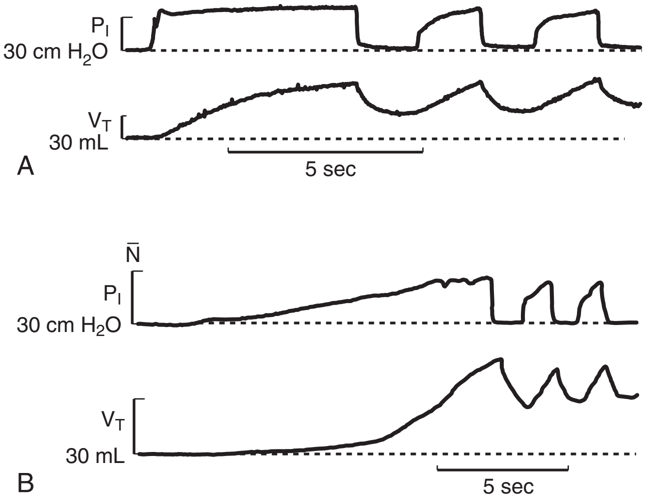

Figure 26–9. **A**, Longitudinal trace of inflation pressure (P_I) and tidal volume (V_T) showing prolonged square-wave inflation and formation of functional residual capacity (FRC). **B**, Longitudinal trace of P_I and V_T showing slow-wave inflation with formation of FRC. *(From Vyas H et al: Physiologic responses to prolonged and slow-rise inflation in the resuscitation of the asphyxiated newborn infant,* J Pediatr *99:6535, 1981.)*

These studies with anesthetized animals show the basic principles and effect of a sustained inflation, but further evaluation of the benefits and risks of sustained inflation during neonatal resuscitation are still needed. Most human preterm infants breathe at birth, and the application of a fixed sustained inflation pressure may have a different effect. From these studies, when resuscitating apneic infants, an initial sustained inflation should be considered to aid the early formation of FRC and promote gas exchange.

CONTINUOUS DISTENDING PRESSURE (POSITIVE END-EXPIRATORY PRESSURE OR CONTINUOUS POSITIVE AIRWAY PRESSURE)

Distending pressure is applied to the airways usually through the nose or a cut-down endotracheal tube. The beneficial effects[30] result from (1) splinting the airways open; (2) enhancing lung expansion, and promoting the formation and retention of a residual lung volume at end expiration, preventing alveolar collapse; (3) conserving surfactant on the alveolar surface; (4) reducing ventilation-perfusion mismatch and right-to-left shunting; (5) improving oxygenation; (6) improving lung compliance; (7) reducing airway resistance by dilating the larynx and airways; (8) reducing upper airway occlusion by decreasing upper airway resistance and increasing the pharyngeal cross-sectional area; (9) reducing the work of breathing; (10) stabilizing the respiratory pattern; (11) reducing obstructive apnea; (12) stabilizing the chest wall, and counteracting paradoxical movements; (13) facilitating lung fluid clearance; and (14) after extubation reducing the proportion of infants requiring reintubation.

Although PEEP is always used during mechanical ventilation in the NICU, the 2005 ILCOR guidelines do not stipulate the use of PEEP during PPV of sick preterm infants at birth.[22] A survey by Graham and Finer[13] showed that only 59% of neonatologists in the United States use PEEP during neonatal resuscitation. The lungs of preterm infants are immature, surfactant-deficient, partially liquid-filled, and prone to collapse at end expiration. After an inflation without PEEP, lung volume is lost, and atelectrauma can develop during the next inflation.[6] In a small clinical study, Finer and associates[12] showed that application of PEEP was feasible in the delivery room, but this did not improve outcome.

Animal studies support the use of PEEP at birth, however, and have shown that it protects against lung injury and improves lung compliance and gas exchange.[47] Oxygenation and an increase in heart rate depend on lung aeration and FRC to facilitate effective gas exchange. Thome and colleagues[53] reported that in ventilated preterm infants, FRC is mainly determined by PEEP. Experimental studies of preterm rabbit pups ventilated from birth using phase contrast x-ray imaging and plethysmography have shown that PEEP has an essential role in facilitating lung aeration, accumulating FRC, and preventing distal airway collapse at end expiration. In similar studies, the effect of PEEP combined with an initial long inflation showed clearly that during ventilation at birth PEEP was needed to create and maintain FRC. In the presence and absence of a sustained inflation, without PEEP, no FRC was maintained.[52] On the basis of all these studies, we recommend using PEEP during ventilation of preterm infants at birth to aid lung aeration and the formation of FRC.

It is difficult to predict optimal PEEP for each infant and how it should be changed as the lungs aerate,[8,57] although infants with the highest oxygen requirements usually have the lowest FRC.[57] Studies of surfactant-treated preterm infants showed that increasing PEEP to 4 to 6 cm H_2O increased FRC and improved oxygenation, but also slightly increased $Pa\text{CO}_2$.[8,9] No increase in $Pa\text{CO}_2$ was noted in animal studies with a controlled tidal volume, however.[38,39] PEEP levels of 8 cm H_2O could be considered for resuscitation of preterm infants. Randomized, controlled trials of different levels of PEEP during resuscitation of human infants at birth are required.

Continuous Positive Airway Pressure

When interpreting the studies of early nasal CPAP as primary strategy for infants with respiratory distress, it is important to realize that nasal CPAP was started in the delivery room during resuscitation and in the presence of signs of respiratory distress in only a few studies.[31,47,48] The starting time for early nasal CPAP is important because a noncompliant lung collapses and lung volume is not maintained if CPAP is not given immediately to keep the lung open.[30] A randomized, controlled trial of two techniques of giving respiratory support to preterm infants after birth compared a 10-second prolonged inflation followed immediately by CPAP or PEEP with CPAP not started until the infant was in the NICU. The trial showed more infants were subsequently intubated and ventilated in the group who did not receive the prolonged inflation and CPAP or PEEP in the delivery room.[48]

The low intubation rate in the early nasal CPAP cohort studies could be explained by the fact that a relatively high fraction of inspired oxygen ($F\text{IO}_2$) threshold (≥0.6) was used for intubation.[50] It has been shown, however, that preterm infants also benefit from selective intubation and early nasal CPAP when combined with a lower $F\text{IO}_2$ threshold (≤0.4) for intubation.[50] Starting early nasal CPAP in breathing infants with respiratory difficulties is feasible.[31] In a large international randomized, controlled trial (COIN-trial), nasal CPAP started at 5 minutes was compared with elective intubation in the delivery room and showed a reduced need for oxygen at 28 days in the nasal CPAP group, but only a trend toward a reduction in death or bronchopulmonary dysplasia at 36 weeks' corrected age.[31] There was a higher incidence of pneumothoraces in the nasal CPAP group. The hospital outcomes for the CPAP and intubation groups were basically similar. It seems reasonable to start facemask or nasal prong CPAP from birth in very preterm infants at no less than 5 cm H_2O. If this treatment is inadequate to support breathing (apnea, increasing $F\text{IO}_2$, high and rising CO_2), intubation, ventilation, and treatment with surfactant should be instituted as soon as possible.

EQUIPMENT

Pressure Delivering Device

O'Donnell and colleagues[32] performed a survey in 40 neonatal centers in 19 countries to determine which equipment was used to resuscitate newborns at birth. Most centers (83%) used self-inflating bags and masks; 25% used flow-inflating bags; and 30% used the Neopuff Infant Resuscitator (Fisher & Paykel, Auckland, New Zealand), a mechanical pressure-limited T-piece device.

A self-inflating bag (Fig. 26-10A) re-expands, after compression, by elastic recoil, and no gas source is needed. Commonly, a self-inflating bag of 240 mL is used. This bag is more than adequate to deliver the tidal volume required (approximately 5 mL/kg) if there is a leak-free seal with the face. The pressure delivered depends on how hard the bag is squeezed. For most resuscitations, a gentle squeeze with a finger and thumb is all that is required as long as there is no leak between the mask and face. A pressure-limiting valve prevents a pressure of more than about 40 cm H_2O being delivered unless it is overridden. A self-inflating bag cannot be used to deliver a prolonged inflation of more than 1 second, PEEP, or CPAP. It is not ideal for ventilating premature infants after birth. If a PEEP valve is attached, some PEEP (but not CPAP) can be delivered, but it is extremely rate dependent, and there is very little PEEP at rates less than 60/min because of the decay in pressure.

A flow-inflating bag (see Fig. 26-10B) needs a source of piped gas to be inflated. Also, the pressure delivered depends on how hard the bag is squeezed, and a gentle squeeze is enough in most cases. A variable pressure-limiting valve may be attached to prevent a high pressure being delivered. The user controls the PEEP by controlling the rate of gas escaping from the bag during expiration. This is difficult and can lead to transient high PEEP. Compared with a self-inflating bag,

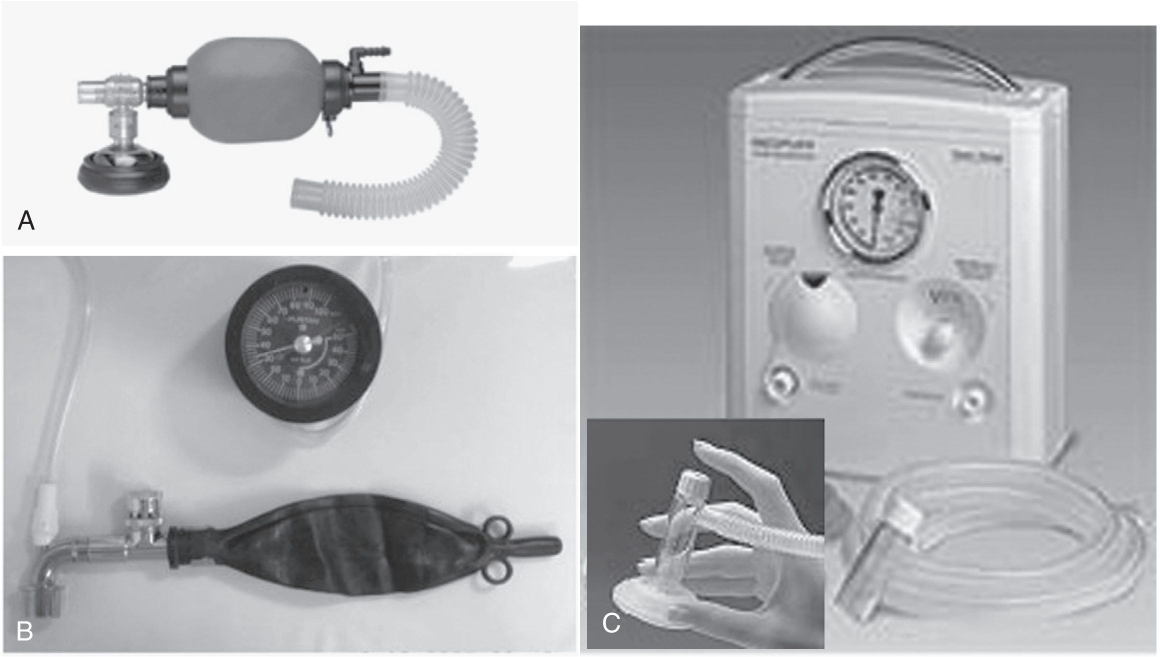

Figure 26–10. Neonatal resuscitation devices. **A**, A 240-mL self-inflating bag (Ambu Baby Resuscitators; Ambu, Ballerup, Denmark) with an oxygen reservoir attached. A gas source or flow into the bag can be used, but is not needed because a self-inflating bag re-expands, after compression, by elastic recoil. **B**, A flow-inflating bag (anesthesia bag) with a pressure dial attached. A flow-inflating bag needs gas flow to inflate it. The user controls the rate of gas escaping from the bag to maintain positive pressure during expiration. **C**, A T-piece device (Neopuff Infant Resuscitator; Fisher & Paykel, New Zealand). The T-piece device is a pressure-limited mechanical device, delivering gas flow through a T-piece to a mask, endotracheal tube, or nasopharyngeal tube. The T-piece has a white valve on the top that controls the rate of gas escape and can be adjusted to set a positive end-expiratory pressure (PEEP) for a given gas flow. Peak inflation pressure (PIP) is set by adjusting a valve in the main box. Inflation is generated by occlusion of a hole in the PEEP valve with a finger. PIP and PEEP are consistent and constant for every inflation.

the technique of using a flow-inflating bag is difficult. It should not be used unless the operator is experienced and skilled with this technique.[11] A prolonged inflation can be delivered by a skilled operator. A flow-inflating bag cannot be used to deliver CPAP.

A T-piece device (see Fig. 26-10C) is a pressure-limited mechanical device, delivering gas flow through a T-piece to a mask, endotracheal tube, or nasal tube. The T-piece has a valve that can be adjusted to set a PEEP for a given gas flow. PIP is generated by occlusion of a hole in the valve with a finger. The inflation time depends on how long the hole is occluded. An advantage of a T-piece device is that the PIP and PEEP are constant for each inflation, provided that there is not a large leak between the mask and face. It is easy to use, even by inexperienced operators.[20] Because neither a self-inflating nor a flow-inflating bag can be used to give CPAP, a T-piece device is most appropriate for respiratory support of preterm infants immediately after birth.[11,20,33]

Although inefficient mask resuscitation may not achieve adequate PIP and tidal volume exchange, some neonates benefit because inflation pressures may stimulate the Head paradoxical reflex.[29] In the Head paradoxical reflex, a neonate responds to an inflation by making a large inspiratory effort. This may be responsible for the first effective inspiratory volume during resuscitation and the first appearance of FRC.[4]

Facemasks

A facemask is commonly used for initial ventilation after birth. An airtight seal between mask and face is important for successful ventilation.[1] Achieving this seal can be difficult,[11] and leak at the mask is a common reason for inadequate ventilation or failure of the resuscitation.[41] The average mask leak is about 60%. Even when the set inflation pressure is achieved with a T-piece device, large leaks can occur in the presence of a high gas flow into the system.[33,59] With variable leaks, variable tidal volumes are delivered, and some are too low and others dangerously large.

The appropriate size of facemask must seal around the mouth and nose, but not cover the eyes or overlap the chin. A range of sizes must be available for infants of different sizes. There is little evidence that leakage is less with a round mask with a cushioned rim.[35] O'Donnell and colleagues[33] showed no difference in leak between round or anatomically shaped facemasks. Improved techniques of holding facemasks can be taught.[58] An accurate position can be obtained when the right-sized mask is rolled upward onto the face from a finger on the chin tip and reduces the leak at the orbital margin (Fig. 26-11).[58] An even downward pressure onto the mask and an equal upward pressure from jaw lift with the fourth and fifth fingers is the best way to reduce mask leak (see Fig. 26-11).[58]

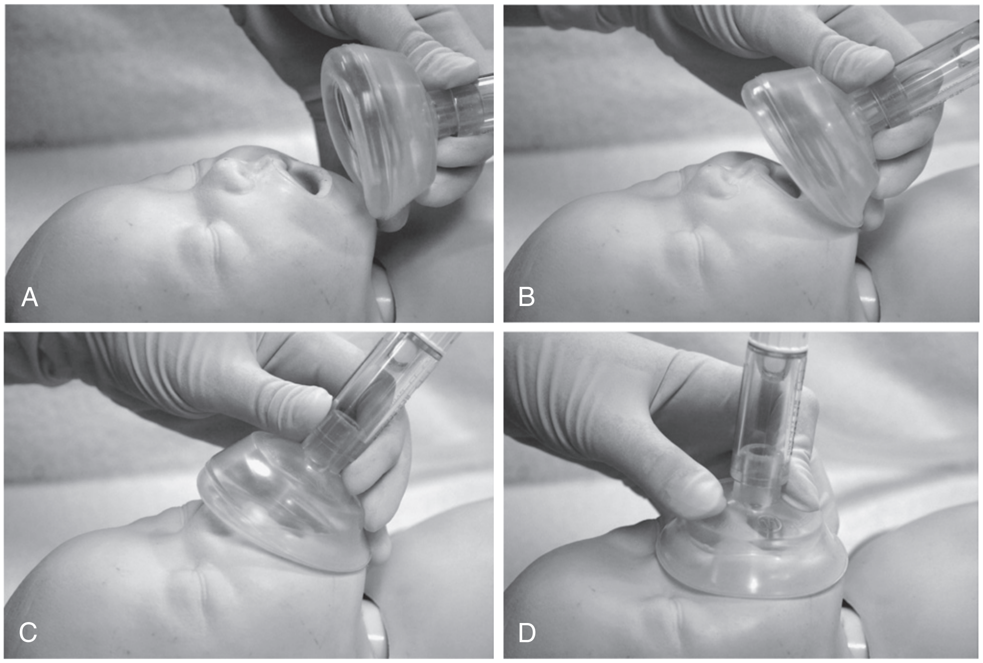

Figure 26–11. Improved mask placement technique—rolling up from the chin. An accurate position can be obtained when the mask is rolled upward onto the face from the chin tip, and this reduces the leak at the orbital margin.[58] An even downward pressure onto the mask and an equal upward pressure from jaw lift is the best way to reduce mask leak. *(Photos courtesy of Fiona Wood.)*

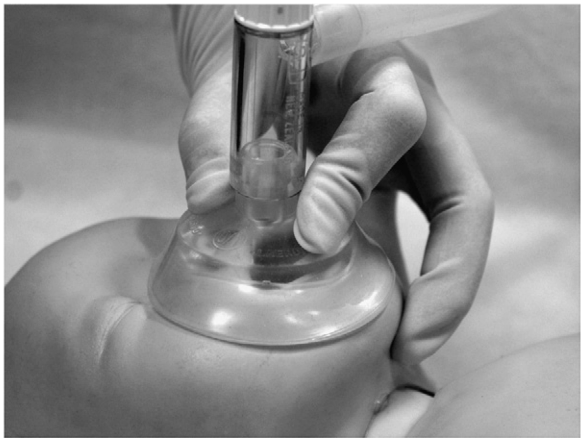

Figure 26–12. For a round Laerdal mask, the "two-point top hold" provides the best mask seal.[58] The thumb and index finger apply balanced pressure to the top flat portion of the mask where the silicone is thickest. The stem is not held, and the fingers should not encroach onto the skirt of the mask.[41] The downward pressure on the mask is counteracted by an upward pressure lifting the chin with the second and third fingers. *(Photo courtesy of Fiona Wood.)*

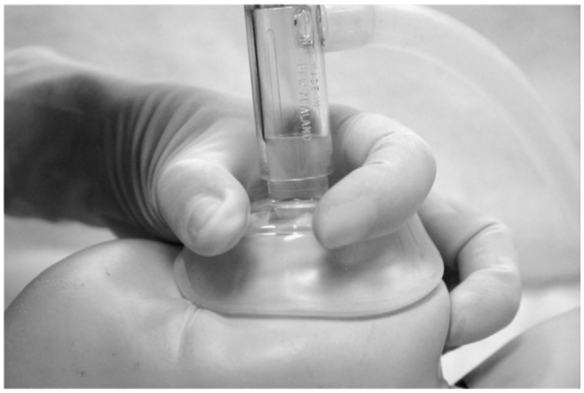

Figure 26–13. For the Fisher & Paykel round mask, the "OK rim hold" provides the best seal.[58] The thumb and index finger form a C shape (as in the "OK" hand gesture) placed around the top flat portion of the mask, applying an even distribution of pressure supporting the outer edge and not encroaching onto the skirt of the mask.[1] The downward pressure on the mask is counteracted by an upward pressure lifting the chin with the second and third fingers. *(Photo courtesy of Fiona Wood.)*

There are different methods of holding a mask to reduce leak. For a round Laerdal mask, "the two-point top hold" led to the best seal (Fig. 26-12).[58] This is when the thumb and index finger apply balanced pressure to the top flat portion of the mask where the silicone is thickest. The stem is not held, and the fingers should not encroach onto the skirt of the mask because this causes the rim to kink.[41] For the Fisher & Paykel round mask, the "OK rim hold" gave the best seal (Fig. 26-13).[58] This is when the thumb and index finger form a "C" shape (as in the "OK" hand gesture) placed around the top flat portion of the mask, applying an even distribution of pressure to the outer edge and not encroaching onto the skirt of the mask so that it stabilizes the distensible top part of the mask.[1] The fear of large facemask leaks leads some clinicians to apply excessive pressure to the mask and face. This pressure can cause obstruction to the airway by distorting the nose, mouth, and chin position.

Single Nasal Tube

An alternative to avoid facemask leak is to use single or double nasal prongs. Segedin and associates[44] examined whether the nasal or oral airway was the better route for resuscitation using a Laerdal infant mask and observing chest expansion and capnography. They showed that manual ventilation was more often successful when given via a nasal tube. In a randomized trial, Capasso and colleagues[5] compared binasal nasal prongs and the Rendall-Baker face mask during neonatal resuscitation of infants with moderate asphyxia. Neonates resuscitated with nasal prongs had significantly less intubation (0.6% versus 6.3%; $P < .001$) and chest compressions (1.7% versus 8.3%; $P < .001$). The Rendall-Baker mask is probably the least effective for neonatal ventilation, however. Using a single nasal tube instead of a facemask in studies during stabilization of preterm infants at birth, Pas and coworkers[48] and Lindner and associates[26] observed less frequent intubations in the delivery room. In these studies, there were many confounding factors, however, other than comparing facemask versus nasal tube.

Laryngeal Mask

The laryngeal mask airway is a device that can be used to provide ventilation when positive pressure with a facemask fails to achieve effective ventilation, and attempts at endotracheal intubation have been unsuccessful. The laryngeal mask airway may be helpful for infants with congenital anomalies involving the mouth, lip, or palate, such as Pierre Robin syndrome. The size 1 neonatal device is a soft elliptical mask with an inflatable rim attached to a flexible airway tube. The device is inserted into the infant's mouth, and an index finger is used to guide the device along the infant's hard palate until the tip nearly reaches the esophagus. No instruments are used. When the mask is inserted, the rim is inflated. The inflated mask covers the laryngeal opening, and the rim conforms to the contours of the hypopharynx occluding the esophagus with a low-pressure seal. The airway tube has a standard 15-mm adapter that can be attached to either a resuscitation bag or a ventilator. A small balloon attached to the rim is used to monitor inflation of the mask. Reusable and disposable versions are commercially available.

There is inadequate evidence to recommend laryngeal mask airway devices for routine neonatal resuscitation. They have been shown to be effective for ventilating full-term neonates.[36] A laryngeal mask airway may be very useful for larger infants with upper airway abnormalities that make intubation difficult; however, there are no laryngeal mask airway devices small enough for preterm infants less than 1500 g. The device cannot be used to suction meconium from the airway.

Endotracheal Tube

There are no strict criteria for tracheal intubation. The ILCOR guidelines state that intubation can be considered at several stages during resuscitation.[22] Indications for endotracheal intubation vary depending on the gestational age of the infant, degree of respiratory depression, response to noninvasive ventilation, and skill and experience of the resuscitator. The following can be used as a guideline: Tracheal intubation should be performed if noninvasive ventilation does not increase the heart rate, or if the infant continues to be apneic despite adequate ventilation. Infants without a detectable heartbeat and who are floppy should be intubated and ventilated as soon as possible after birth.

Some experts recommend early elective intubation of preterm infants (<29 weeks' gestation), whereas others recommend CPAP via a mask or nasal prongs immediately after birth if the infant is breathing.[47] Other experts advocate elective intubation and administration of surfactant in the delivery room to all very preterm infants regardless of their condition. In a large randomized, controlled trial, it was shown that many very preterm infants can be treated with nasal CPAP without intubation, ventilation, and immediate surfactant treatment.[31]

The equipment needed for endotracheal intubation is listed in Box 26-4. Table 26-3 provides guidelines for endotracheal tube sizes and depth of insertion. A laryngoscope with a straight blade (size 0/00 for preterm and size 1 for term infants) is recommended, although some experienced clinicians use curved blades.

Intubation Procedure

Insufficient data are available to recommend tracheal intubation by oral or nasal route. One route of intubation does not seem to be preferable to the other.[45] The infant should be placed supine in a "sniffing position" (Fig. 26-14) because hyperextension or flexion of the neck makes the glottis hard to visualize. The tip of the laryngoscope should be advanced over the tongue to the vallecula or on top of the epiglottis and elevated gently to reveal the vocal cords (Fig. 26-15). If the laryngoscope is advanced initially too deep, the tip is in the lower pharynx, and the larynx cannot be seen. The laryngoscope must support the tongue out of the line of vision of the larynx. The tongue is held slightly toward the left side of the mouth to have adequate space to see the larynx and pass

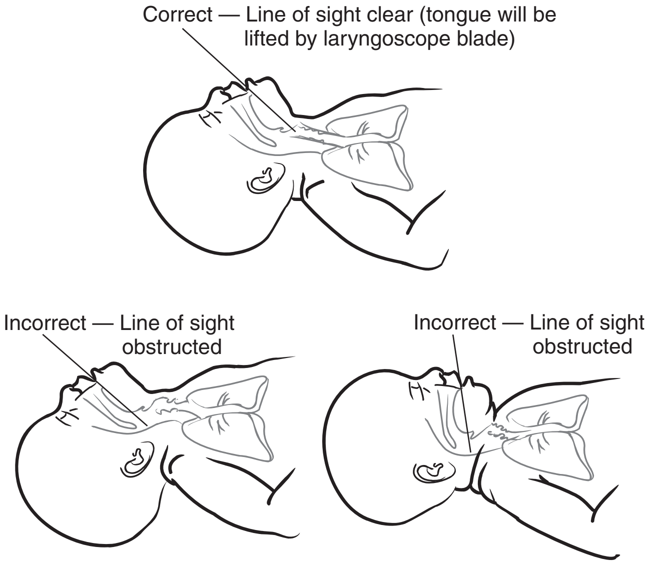
BOX 26–4 Equipment for Endotracheal Intubation

- Pressure delivering device (T-piece device or self-inflating bag [manometer optional])
- Neonatal masks, preterm and term infant sizes
- Laryngoscope with blades (straight blade, Miller size number 00, 0 for preterm, and number 1 for term infant)
- Endotracheal tubes (2.5, 3.0, 3.5, 4.0 mm ID); they should be of uniform diameter, without a shoulder, with a standard curve, radiopaque, and with marks to indicate depth of insertion
- Endotracheal tube stylet
- Magill neonatal forceps
- Sterile scissors
- Neonatal stethoscope
- Exhaled CO_2 detector (Pedi-Cap)
- Oxygen, oxygen flowmeter with air blender
- Pulse oximeter for measuring heart rate and oxygen saturation
- Suction apparatus and suction catheters (5, 6, 8, and 10 Fr)
- Equipment to secure endotracheal tube, appropriate adhesive tape to attach tube to face

TABLE 26–3 Guidelines for Endotracheal Tube Sizes and Depth of Insertion

Weight (g)	Gestation (wk)	Endotracheal Tube Size (mm ID)	Orotracheal Tube Length (cm) from Upper Lip	Nasotracheal Tube Length (cm) from Nasal Flare
500-750	<28	2.5	6.5	7.5
750-1000	<28	2.5	6.5-7.0	7.5-8.0
1000-2000	28-34	3.0	7.0-8.0	8.0-9.0
2000-3000	34-38	3.0/3.5	8.0-9.0	9.0-10.0
>3000	>38	3.5/4.0	>9.0	>10.0

Note: Depth can be calculated as weight in kg + 6 cm for oral intubation (+ 1 cm for nasal intubation).



Correct — Line of sight clear (tongue will be lifted by laryngoscope blade)
Incorrect — Line of sight obstructed
Incorrect — Line of sight obstructed

the endotracheal tube. Cautious cricoid pressure may be helpful by bringing the larynx into view.

After insertion of the endotracheal tube, the tube marker should be visible just above the larynx. If it cannot be seen, the tube has been inserted too far. The tube should be secured with the appropriate centimeter side mark (see Table 26-3) located at the upper lip, typically estimated as 6 cm plus the weight in kilograms. Variation in head position may alter the depth of insertion and predispose to extubation or bronchial intubation.[42] A stylet in the endotracheal tube can be used to facilitate intubation, but care must be taken not to protrude the stylet beyond the tip and damage the trachea. When removing the stylet, great care must be taken not to dislodge the tube.

The position of the endotracheal tube in the trachea must always be verified. Positioning can be verified by visualizing the tube passing through the vocal cords, listening to both axillae with a stethoscope, observing mist inside the endotracheal tube during expiration, observing chest movements during inflations, and noting an increase in heart rate. None of these maneuvers are foolproof, however, and all take time. It is now recommended to use an end-tidal CO_2 detector on the outer end of the endotracheal tube to verify correct tube placement quickly.[40] The end-tidal CO_2 detector shows CO_2 leaving the tube within six inflations. The depth of tube insertion should be assessed by checking the measurement on the tube at the lips, symmetric chest movements and breath sounds, and a chest radiograph soon after the infant is admitted to the nursery.

PART 3

Oxygen Therapy

Maximo Vento and Ola Didrik Saugstad

USE OF OXYGEN IN PERINATAL ASPHYXIA AND RESUSCITATION

Oxidative Stress: Pathophysiologic Background

Asphyxia is characterized by prolonged periods of ischemia and hypoxia, which lead to specific cellular changes affecting enzyme activities, mitochondrial function, cytoskeletal structure, membrane transport, and antioxidant defenses. All of these changes collectively predispose tissue to reoxygenation injury.[4,12,24] During hypoxia, limited oxygen availability decreases oxidative phosphorylation, resulting in a failure to resynthesize energy-rich phosphates, including adenosine 5′-triphosphate (ATP) and phosphocreatine. The membrane ATP-dependent Na^+/K^+ pump is altered, favoring the influx of Na^+, Ca^{2+}, and water into the cell, producing cytotoxic edema in addition to eliciting numerous metabolic pathways that are injurious to various structural components of the cell. Adenine nucleotide catabolism during ischemia results in accumulation of hypoxanthine, which is subsequently converted into toxic reactive oxygen species on the reintroduction of molecular oxygen during resuscitation, provided that xanthine oxidase is available (Fig. 26-16).[27]

In the endothelium, ischemia promotes expression of certain proinflammatory gene products (e.g., leukocyte adhesion molecules, cytokines) and bioactive agents (e.g., endothelin, thromboxane A_2), while repressing other “protective” gene products (e.g., prostacyclin, nitric oxide). Ischemia induces a proinflammatory state that increases tissue vulnerability to further injury on reperfusion.

Reperfusion and reoxygenation of the ischemic tissues results in the formation of toxic reactive oxygen species, including superoxide anions, hydrogen peroxide (H_2O_2), hydroxyl radicals, and nitrogen reactive species, especially peroxynitrite.[8,12,24] Normally, hypoxanthine accumulated during the ischemic phase is oxidized by xanthine dehydrogenase to xanthine in the cells containing this enzyme. During ischemia, xanthine dehydrogenase is converted to xanthine oxidase by specific proteases, however. Xanthine oxidase uses oxygen as substrate and during hypoxia-ischemia is unable to catalyze the conversion of hypoxanthine (resulting in the buildup of excess tissue levels of hypoxanthine). When oxygen is reintroduced during reperfusion and reoxygenation, conversion of the excess hypoxanthine by xanthine oxidase results in the formation of reactive oxygen species, and in the presence of nitric oxide, in the formation of reactive nitrogen species. Xanthine oxidase in humans is mainly restricted to the liver and intestine. It has been shown, however, that xanthine oxidase leaks out into the blood after hypoxia and hypotension, and the hypoxanthine-xanthine oxidase system may be detrimental in all parts of the body. Many other oxygen radical generating systems are presently well described.[27,36]

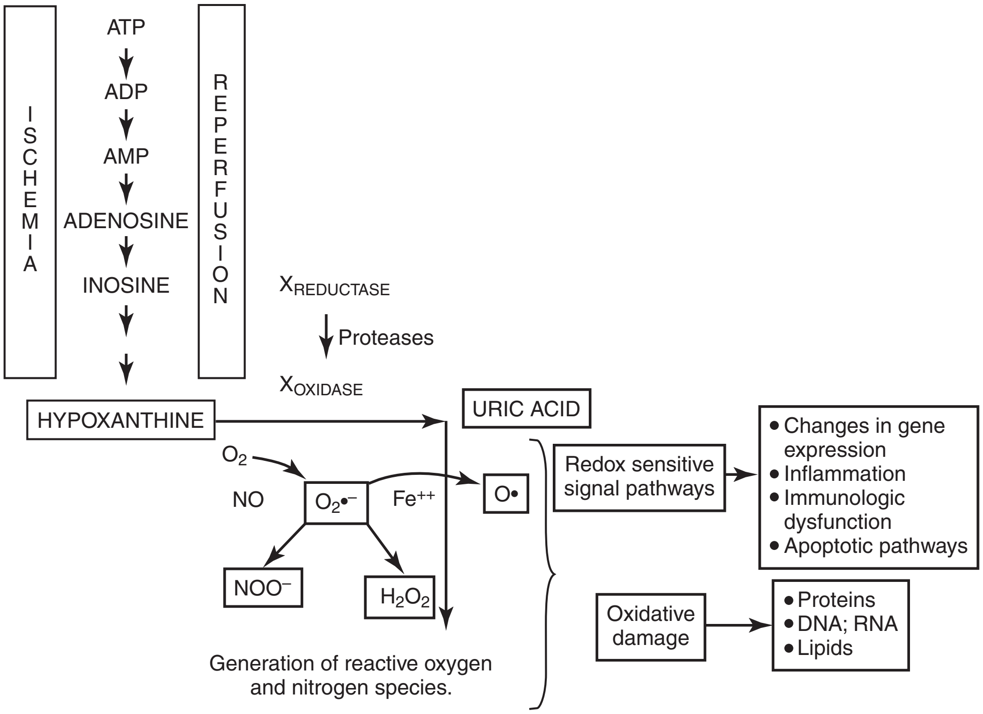

Figure 26–16. During hypoxia, ATP is exhausted, and complete rebuilding is not achieved. Purine derivatives (e.g., hypoxanthine) accumulate. During reoxygenation, specific proteases transform xanthine reductase ($X_{REDUCTASE}$) into xanthine oxidase ($X_{OXIDASE}$), which uses oxygen as substrate generating a burst of reactive oxygen species such as superoxide anion ($O_2\cdot^-$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($O\cdot$). In the presence of ferrous iron (Fe^{++}), Fenton chemistry generates great amounts of superoxide anion. Superoxide anion easily combines with abundant nitric oxide (NO) generating peroxynitrite ($NOO\cdot$), an extremely aggressive nitrogen free radical. Free radicals are capable of damaging nearby molecules and organelles, but also act as signaling molecules causing changes in gene expression, promoting inflammation, altering immune response, and inducing apoptosis.

Reactive oxygen species and reactive nitrogen species are potent oxidizing and reducing agents that directly damage cellular structures. They are able to peroxidize membranes, structural proteins and enzymes, and nucleic acids. In addition, they are known to be extremely important regulators of intracellular signaling pathways that modulate DNA and RNA synthesis, protein synthesis, and enzyme activation, and directly influence the cell.[27]

A vast array of enzymatic and nonenzymatic antioxidants has evolved in biologic systems to protect cellular structures against the deleterious action of free radicals.[17] Among the enzymes, the most important are superoxide dismutase, catalase, and glutathione peroxidase. The major nonenzymatic intracellular antioxidant is reduced glutathione, a tripeptide able to reduce free radicals by establishing a bond with another reduced glutathione molecule, forming oxidized glutathione and releasing one electron. Thiol-di-sulfide strategy is extremely important to maintaining the reducing state in the cytoplasm and the cell redox status, essential for cell reproduction and maturation.

Oxidative stress in a biologic system is defined as the imbalance of pro-oxidants and antioxidants in favor of pro-oxidants.[15] Different biomarkers of oxidative stress have been used in biology and medicine. An indirect way of measuring oxidative stress is the detection of increased activity of antioxidant enzymes, such as superoxide dismutase, catalase, glutathione peroxidase, or glutathione redox cycle enzymes. Another measure is to analyze the oxidized form of a nonenzymatic molecule such as oxidized glutathione. An increased concentration of oxidized glutathione or a decreased ratio of reduced to oxidized glutathione may indirectly reflect a pro-oxidant status.

For clinical purposes, among the most reliable markers of oxidative stress are markers derived from the oxidant alteration of biologic molecules that have the characteristics of being stable, reproducible, and easily measurable in biologic fluids. Urinary markers of oxidative stress are extremely valuable in neonatology because urine sampling is readily available allowing serial measurements without the need of supplementary blood sampling. In this regard, oxidation of circulating phenylalanine by hydroxyl radicals leads to the formation of ortho-tyrosine (O-tyr). This specific metabolite is not synthesized by any physiologic metabolic pathway; its concentration in urine specifically reflects the oxidation of phenylalanine by hydroxyl radicals.[25] Other relevant urinary biomarkers are oxidative bases of DNA. Specifically, guanine is prone to oxidation by hydroxyl radicals, and its lesion product 8-hydroxyguanine (8-oxo-Gua) and its 2′-deoxynucleoside equivalent 7,8-dihydro-2′-de-oxy-guanosine (8-oxo-dG) are highly mutagenic. Its urinary elimination perfectly reflects nuclear attack by hydroxyl radicals.[5] In recent experiments performed in a piglet model of hypoxia and reoxygenation, urinary elimination of metabolites O-tyr and 8-oxo-dG correlated significantly with the amount of oxygen used on reoxygenation.[48] Finally, isoprostanes and isofurans, which are noncyclooxygenase oxidative derivatives of arachidonic acid, are considered at present the most reliable markers of lipid peroxidation. These compounds are chemically stable, formed in vivo, present in all organic fluids and tissues, and not affected by dietary content of lipids. Isofurans reflect oxidation in a high oxygen atmosphere and isoprostanes in a normoxic environment.[29,31]

Oxidative Stress: Differences between Resuscitation with 100% Oxygen and Room Air

In the absence of severe lung disease or cyanotic congenital heart disease, resuscitation with 100% oxygen causes hyperoxemia ($PaO_2 \geq 100$ mm Hg), and very high levels have been described. By contrast, resuscitation with room air increases the PaO_2 to physiologic levels only (i.e., approximately 70 to 80 mm Hg). Biologic markers that are indicative of oxidative stress, such as oxidized glutathione or antioxidant enzyme activity, correlate significantly with the partial pressure of oxygen achieved in arterial blood. Newborns resuscitated with pure oxygen have a higher degree of oxidative stress at birth than infants resuscitated with room air.[54]

In one study, there was evidence of oxidative stress for 4 weeks postnatal age in infants resuscitated with 100% oxygen. These infants had a decreased ratio of total blood reduced glutathione to oxidized glutathione and oxidized DNA bases in urine at 1 month of life. No such effect has been observed in infants resuscitated with room air (Fig. 26-17).[51]

Hyperoxemia has also been associated with a series of negative side effects, including increased oxygen consumption and metabolic rate, increased activation of leukocytes and endothelial cells, and increased formation of reactive oxygen species and reactive nitrogen species.[12,13] Prolonged vasoconstriction of cerebral arteries has also been shown. In a study involving premature infants younger than 33 weeks' gestational age at 24 hours, cerebral blood flow was reduced by 20% in infants given 80% oxygen compared with infants in whom room air was used. This finding is in line with more recent studies in newborn rats showing that the use of 100% oxygen for resuscitation reduces cerebral blood flow compared with room air resuscitation.[10,26]

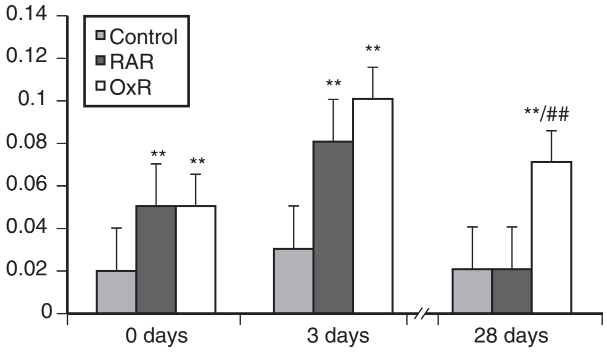

Figure 26–17. Ratio of oxidized glutathione to reduced glutathione in asphyxiated newborns resuscitated with room air (RAR) or 100% oxygen (OxR) determined at 0 (birth), 3, and 28 days of life. $**P < .01$ versus control; $\#\#P < .01$ versus RAR.

ROOM AIR VERSUS PURE OXYGEN FOR RESUSCITATION OF THE NEWBORN

The traditional approach during resuscitation was to use 100% oxygen.[1,2,30] In view of increasing knowledge of oxidative stress, the question arises: What is the optimal oxygen supplementation during resuscitation of a newborn?[43] Using a term newborn, a distinction is made between immediate procedures performed within minutes after birth and procedures performed later in newborn life. The effect of hyperoxia might be completely different at birth than later in the neonatal period.

Animal Studies

Animal studies have shown that after a period of severe hypoxia, physiologic functions such as blood pressure and blood flow to various organs, including the brain, are restored equally efficiently with 21% and 100% oxygen. Evoked potentials and biochemical indicators such as base deficit and hypoxanthine are restored efficiently using room air for resuscitation.[43,45]

More recent animal studies have indicated a potential advantage in using 21% instead of 100% oxygen. A burst of oxygen radicals is produced in the brain[11] and in the lung when the newborn is resuscitated with pure oxygen, in contrast to room air, with which no such increase has been detected. The H_2O_2 concentration in leukocytes from the sagittal sinus increased significantly in newborn hypoxic piglets resuscitated with 100% oxygen, in contrast to piglets given 21% oxygen. The nitric oxide concentration in the brain also tended to become higher if pure oxygen was used compared with ambient air for resuscitation of piglets. The stage might be set for a higher production of reactive nitrogen species and peroxynitrite if 100% oxygen is used.[19-21]

Based on data obtained from resuscitation of asphyxiated newborn piglets, using a model in which asphyxia was induced by pneumothorax, a significantly better short-term neurologic outcome was found in animals resuscitated with 21% oxygen than with 100% oxygen. In another study, brain cell membrane function was evaluated by measuring the activity of Na^+,K^+-ATPase. This membrane-bound enzyme is needed to maintain cell membrane integrity. Asphyxiated animals resuscitated with pure oxygen had an inhibition of Na^+,K^+-ATPase 2 hours after resuscitation was started, in contrast to animals given 21% oxygen, in which Na^+,K^+-ATPase activity had reached baseline at this time.[14,49]

There are also clear indications that resuscitation with 100% oxygen augments inflammatory processes in the myocardium and the brain more than 21% oxygen. In a study using cord occlusion of fetal lambs, resuscitation with room air restored blood pressure as fast as when using 21% oxygen. In the cortex and subcortical area, significantly higher levels of proinflammatory cytokines and activities of Toll-like receptors 2 and 4 were found in animals given 100% oxygen.[28]

Some animal studies have shown that cerebral brain microflow is reestablished faster with 100% oxygen. One study in newborn mice found that 100% versus 21% oxygen gave faster cerebral blood flow restoration and poorer short-term and improved long-term recovery.[32] In one study, the slower normalization of cerebral blood flow in animals resuscitated with room air versus animals resuscitated with 100% oxygen almost disappeared, however, if moderate hypercapnia was present. In birth asphyxia, hypercapnia always coincides with hypoxia.[47] Hypercapnia might seem to be an important factor in reestablishing brain flow after asphyxia. As mentioned earlier, other studies have shown that 100% oxygen during normocapnia, in contrast to the use of 21% oxygen, reduces cerebral blood flow.[10]

Pulmonary pressure and flow is restored faster using 100% oxygen compared with the use of 21% oxygen. After 30 minutes, there was no difference, however, in pulmonary resistance. A surprising finding was that when these vessels were tested the next day for reactivity, the animals that had been exposed to 100% oxygen the first 30 minutes of life had a significantly higher reactivity than animals that had been exposed to room air only. It seems that exposure to pure oxygen immediately after birth reduces pulmonary vascular resistance more efficiently in the immediate resuscitation period, but increases the risk for pulmonary hypertension if the newborn is subjected to further insults.[22,23]

At least two studies in newborn animals have shown that morphologic brain injury is augmented when using 100% oxygen compared with 21% oxygen.[3,18] Animal studies have also shown that even in meconium aspiration, resuscitation with room air is as efficient as resuscitation with 100% oxygen, provided that a sufficient tidal volume is given.[50] The results from animal studies quite overwhelmingly indicate that room air resuscitation is in most cases more beneficial than the use of 100% oxygen. Still, there might be clinical conditions such as prematurity with primary lung disease when limited initial supplemental oxygen should be added.

Clinical Data

Several clinical studies have been conducted with the aim of evaluating the efficacy of resuscitation with ambient air compared with pure oxygen. To date, 10 studies including 2133 newborns have been included in randomized or pseudorandomized studies investigating any differences between infants resuscitated with 21% oxygen and 100% oxygen.[34,35,37,46,51-54] It seems that Apgar scores are more depressed, at least at 5 minutes of age, in newborns resuscitated with 100% oxygen compared with 21% oxygen; this is probably because newborns given oxygen take their first breath and cry significantly later than newborns given room air. As shown in a newborn rat model, postnatal hyperoxia may also inhibit peripheral chemoreceptors and delay onset of breathing. Normal, nonasphyxiated newborns delivered vaginally or by cesarean section initiate the first cry almost immediately after birth and attain a sustained pattern of respiration within the first 30 seconds of life. Hypoxic and acidotic asphyxiated infants do not initiate breathing spontaneously, however, and may require PPV. The duration of the resuscitation period directly correlates with the severity of asphyxia and the efficiency of the resuscitation procedure.

In a meta-analysis, the onset of respiration was a mean of 30 seconds later in infants given 100% oxygen compared with infants given room air. The time to first cry in infants resuscitated with room air ranged from 0.6 to 4.5 minutes, whereas infants resuscitated with 100% oxygen took 1.2 to 7 minutes to the first cry (Fig. 26-18). Another study of the duration of resuscitation until asphyxiated infants were able to sustain a spontaneous and regular pattern of breathing revealed that infants resuscitated with room air also needed less time (5.3 ± 1.5 minutes) than infants resuscitated with 100% oxygen (6.8 ± 1.2 minutes) to establish a regular respiration.[46,54]

Meta-analyses and systematic reviews have revealed a significant total reduction of approximately 5% in the neonatal mortality rate in infants resuscitated with room air.[6,33,41,46] A more recent published systematic review showed neonatal mortality of 12.8% in the 100% oxygen group versus 8.2% in the room air group, giving a relative risk (RR) of 0.69 (95% confidence interval [CI] 0.54 to 0.88) for neonatal mortality in infants given 21% oxygen. Number needed to treat is 25. These dramatic results raise several questions, first about the quality of the studies included, and second regarding what was the cause of death in these infants. The studies represent a mixture of blinded and unblinded, multicenter and single-center studies from many countries. Most of the infants were recruited from countries with poor resources. When analyzing separately the children from industrialized countries enrolled in six strictly randomized trials, a significant reduction of 2.8% from 3.9% to 1.1% in neonatal mortality rate was still found (RR 0.32, 95% CI 0.12 to 0.84) in favor of the infants resuscitated with ambient air.[46]

The causes of death can be mainly, but not exclusively, attributed to asphyxia. If oxidative stress is induced in infants resuscitated with pure oxygen, this may lead to alterations of cell function and physiology that place the infant at increased

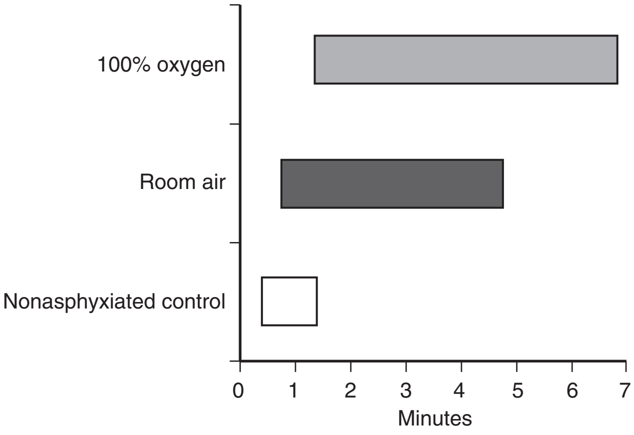

Figure 26–18. Time to first cry in asphyxiated newborns resuscitated with room air or 100% oxygen.

risk. This situation is illustrated in one study finding significantly higher troponin and *N*-acetylglucosaminidase in infants resuscitated with 100% oxygen compared with 21% oxygen indicating more damage to the myocardium and kidney in the infants exposed to pure oxygen.[55] There was also a trend toward a reduction of severe hypoxic-ischemic encephalopathy stage 2 and 3 in the room air-resuscitated infants compared with 100% oxygen-resuscitated infants (RR 0.88, 95% CI 0.72-1.08).[46]

In newborns needing intervention at birth, with an Apgar score of less than 6 at 1 minute and given room air by bag and mask, the median $\text{Sa}O_2$ at 1 minute of age was 65%, with 10th to 90th percentiles ranging from 43% to 80%. At 3 and 5 minutes, the corresponding figures are 85% (60% to 90%) and 90% (73% to 95%). The infants randomly assigned to pure oxygen did not have higher $\text{Sa}O_2$ values over the first 10 minutes of life.[42]

At follow-up,[39] one study showed there were no significant differences in somatic growth or neurologic handicaps between the infants resuscitated with 100% oxygen and the infants resuscitated with 21% oxygen. This study was not originally designed to be a follow-up study and was underpowered to discern clinically important differences in long-term outcome. Two more follow-up studies are underway.

OXYGEN AND RESUSCITATION OF NEONATES OF EXTREMELY LOW GESTATIONAL AGE

Mortality of neonates of extremely low gestational age (≤28 weeks' gestation) has substantially decreased in recent decades; however, morbidity, especially in the lower gestational age segment, remains high. Of neonates of extremely low gestational age, 70% may need active resuscitation in the delivery room. It has been shown in animal experiments that interventions performed in the first minutes of life may cause structural changes in the lung predisposing to chronic lung disease.[16,56] In this regard, the most noxious agents might be oxygen, positive pressure, and volume. Hyperoxia on resuscitation would generate a burst of oxygen free radicals causing oxidative stress especially in this group of patients with an immature antioxidant defense system. As a consequence, oxygen free radicals, which are extremely aggressive molecules, could cause damage to the lung structure predisposing to the development of chronic lung disease.[57] More recent studies have tried to prove the feasibility of resuscitating neonates of extremely low gestational age with low $\text{F}IO_2$. The use of room air (21% oxygen) was unsuccessful in many of these infants, and many had to be switched to 100% oxygen.[58] Resuscitation using an initial $\text{F}IO_2$ of 30% and titration of oxygen needs according to $\text{Sp}O_2$ was successful, however, and substantially diminished the oxygen exposure received by these patients.[9] Healthy neonates of extremely low gestational age achieve $\text{Sp}O_2$ of 75% at 5 minutes after birth, and $\text{Sp}O_2$ of 85% at 8 to 10 minutes (Fig. 26-19), and trying to accelerate oxygen tensions (i.e., "make the baby pink") might put this group of patients at risk of oxygen-induced damage.[44]

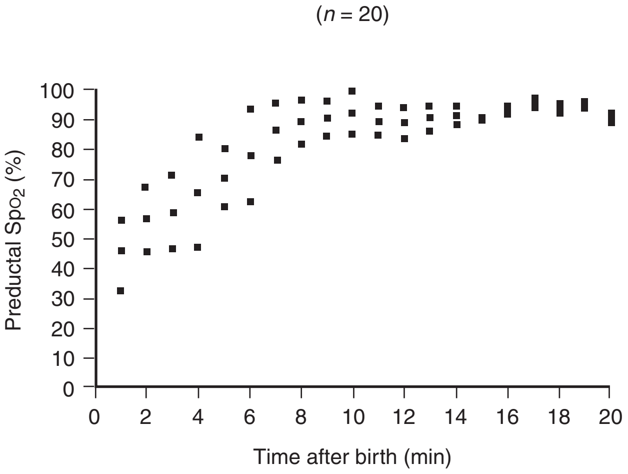

Figure 26–19. Oxygen saturation ($\text{Sp}O_2$) as measured by preductal pulse oximetry in term neonates and neonates of extremely low gestational age (≤28 weeks of gestation) (n = 20) who did not receive active resuscitation or supplemental oxygen immediately after birth. *(Data represented in the graph have been retrieved from Escrig R et al: Achievement of target oxygen saturation in extremely low gestational neonates resuscitated with different oxygen concentrations: a prospective randomized clinical trial,* Pediatrics *121:875, 2008.)*

ROOM AIR VERSUS 100% OXYGEN—OR SOMETHING ELSE

An accumulating body of information raises concerns regarding the use of pure oxygen for routine resuscitation of newborns.[38,40] We believe that pure oxygen should be avoided because it has not been shown to represent an advantage and is potentially detrimental. There is also information that leads us to believe that room air, at least in most cases, is sufficient in term and near-term infants. Whether any oxygen concentration between these extremes is optimal is unknown. In some centers and countries, a compromise has been reached with the recommendation to start with 30% to 40% oxygen.

Although the World Health Organization and several national guidelines have stated that room air is sufficient for so-called basic newborn resuscitation, guidelines still advocate the use of 100% oxygen for resuscitation of newborns. From a worldwide perspective on child health, the sufficiency of room air for resuscitation is an important statement because oxygen is expensive and not at hand at all deliveries around the world. This understanding represents a prerequisite for several studies in countries with poor resources testing out new and simpler resuscitation routines.

To date, the available information indicates that room air is at least comparable to 100% oxygen in resuscitation for term and near-term newborns. If oxygen is available, however, it should always be at hand because a child who does not respond to room air should quickly be given oxygen supplementation. In infants who do not respond with a normal heart rate to room air resuscitation after 90 seconds, we recommend that supplemental oxygen be used, trying to aim at the normal levels of $\text{Sp}O_2$ described in the first minutes of life (see Fig. 26-19). Meanwhile, the Neonatal Resuscitation Program (NRP) of the AHA/AAP is reconsidering the need for their recommendation of 100% oxygen for all resuscitations.

We believe that resuscitation of term or near-term newborns with normal lungs should be started with ambient air. If there is a slow response to the resuscitation as assessed by the heart rate, oxygen could be added after 90 seconds. The optimal strategy should simulate the normal postnatal increase in Sp_{O_2} (see Fig. 26-16) and titrate oxygen supplementation to achieve Sa_{O_2} of 90% after about 5 to 10 minutes.

The data on neonates of extremely low gestational age and infants with extremely low birth weight are still not as robust as in term or near-term infants. Sufficient data show, however, that these infants do not need 100% oxygen at the initiation of resuscitation. Until more data are available, we recommend to start with 25% to 30% oxygen, trying to achieve Sa_{O_2} of 85% within 5 to 10 minutes. Even normal newborns may have Sp_{O_2} as low as 40% during the first 3 to 4 minutes of life.[7]

PART 4

Chest Compression, Medications, and Special Problems

Jay P. Goldsmith

The provision of effective positive pressure ventilation (PPV) (see Part 2) to a depressed neonate is key to optimal neonatal resuscitation in the delivery room. Oxygen occasionally is necessary if the infant remains apneic, or PPV fails to restore spontaneous heart rate to greater than 100 beats/min after 60 seconds, although blended oxygen is recommended, and the risks of hyperoxia are well documented in Part 3 of this chapter. Although recent NRP[2] and ILCOR guidelines[24] advocate the implementation of chest compressions and use of medications for infants who remain bradycardic after 30 seconds of initial steps and 30 seconds of effective PPV, there are compelling data to indicate that if ventilation is managed correctly, chest compression and medication are needed only rarely. In examining 30,839 deliveries, Perlman and Risser[37] noted that with a well-trained team, only 0.12% (39 of 30,839) of deliveries needed chest compressions or medication. The most frequent reason for chest compressions or medication or both in this review was the presence of severe metabolic acidosis at birth (pH <7.00). The authors also found, however, that in 29 of the 39 cases that progressed to chest compressions or medication or both, the infants received either ineffective or improper initial ventilatory support, and they were able to identify five infants who had malpositioning of the endotracheal tube. Commenting on a similar theme in a discussion of resuscitation, Tyson[49] wrote: “We suspect that the most common error in clinical use of epinephrine is that its use distracts the caregivers from recognizing and correcting bradycardia resulting from hypoventilation during resuscitation.”

With an emphasis on the establishment of effective alveolar ventilation, chest compression and medication should be needed in only a very few cases. The problem arises when the resuscitation team mistakenly places the endotracheal tube in the esophagus, or personnel are incapable of placing an endotracheal tube. The first problem can be quickly diagnosed with the use of a CO_2 detector.[57] The second issue can be partially helped by having the correct personnel at the delivery, using correct technique for bag and mask ventilation, and the more frequent use of the laryngeal mask airway for term or near-term infants when an endotracheal tube cannot be placed.

CHEST COMPRESSION

After the initial steps (30 seconds) and effective PPV for 30 seconds, if the heart rate remains low, chest compression should be initiated to help maintain cardiac output (Fig. 26-20). The NRP[2] and ILCOR guidelines[24] recommend initiating chest compressions at heart rates of 60 beats/min or less.

Compression of the chest should occur over the lower third of the sternum, just below an imaginary line drawn between the nipples. Care should be taken not to apply pressure to the xiphoid process at the lower end of the sternum. The sternum should be compressed by using the thumbs with the fingers encircling the chest. Limited available evidence indicates that the alternative two-finger technique previously recommended is not as effective as the thumb technique,[55] and should be reserved for the time during which umbilical venous access is necessary because it allows more open access to the abdomen. When the patient is intubated, some clinicians provide chest compression standing at the head of the infant rather than from the feet, however, eliminating the need for the two-finger technique at any time. Data suggest that a greater mean arterial pressure can be obtained with the thumb method,[12,46] especially if the two-finger technique is used without a backboard. During this aspect of the resuscitation, the individuals providing ventilation and chest compression must position themselves so that they do not interfere with each other, and should communicate regarding the ratio of compressions to ventilations given.

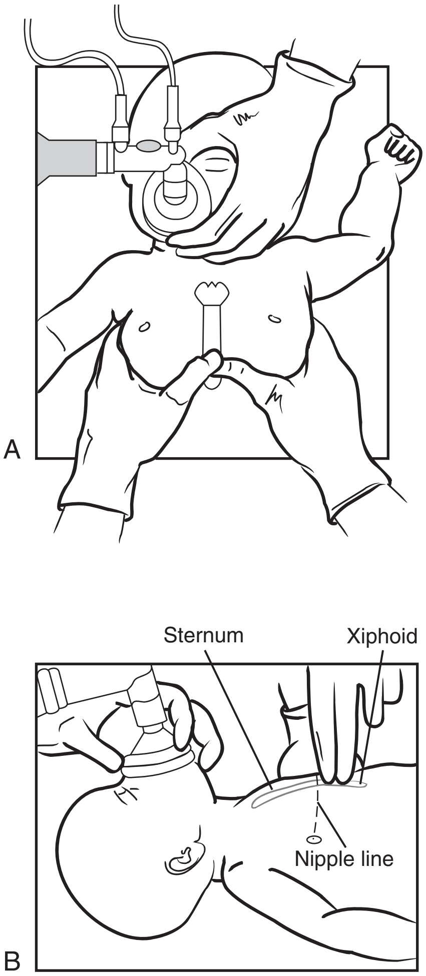

Figure 26–20. **A**, Correct thumb technique of chest compression. **B**, Correct finger position for chest compression. *(Adapted from Kattwinkel J (ed):* Textbook of Neonatal Resuscitation, *5th ed. Copyright American Heart Association/American Academy of Pediatrics, 2006. Used with permission of the American Academy of Pediatrics.)*

Each compression should depress the sternum approximately one third of the anterior-posterior diameter of the chest, or until a palpable pulse is generated. The compression phase should be slightly shorter than the relaxation phase of each stroke to allow for cardiac filling and improved blood flow.[15] A pulse should be palpable with each compression. Having a third person available to check the pulse is helpful. Palpation of a pulse either in a peripheral artery or umbilical cord is often erroneous,[13] however, and is another reason for the use of pulse oximetry or telemetry or both to guide the team's response. It is currently recommended that the chest be compressed 90 times a minute, with a ventilation interposed after each third compression. This approach provides 30 ventilations and 120 events per minute. Within a 2-second period, three chest compressions and a ventilation would occur.[2] It has been suggested that the team should periodically stop chest compressions briefly to see whether the spontaneous heart rate has increased. Stopping interrupts coronary perfusion, however, and may be detrimental.

When the heart rate has increased to 60 beats/min, chest compressions can be stopped. Abdominal organs can be damaged, and ribs can be broken with improperly performed chest compressions. The best way to monitor the effectiveness of chest compression is via arterial blood pressures obtained from a transducer attached to an umbilical artery catheter or a peripheral arterial line. These are not commonly available in delivery rooms, and the team should not take time to establish these lines when moments are critical.

An infant undergoing chest compressions may receive ventilation by a mask, an endotracheal tube, or a laryngeal mask airway. An endotracheal tube has advantages, however, over a mask or laryngeal mask airway in these situations. An endotracheal tube provides more stability and prevents gas from entering the stomach should a compression overlap with a ventilation. Gas in the stomach may raise the diaphragm, making ventilation more difficult. If a bag and mask are used, an orogastric tube should be inserted into the stomach to ensure stomach decompression. A laryngeal mask airway might also be used in a term or near-term infant in this situation, but has less stability than an endotracheal tube and may leak air into the stomach.

It is recommended that ventilations be interposed between compressions.[2,24,26] The reason for coordination, and not simultaneous ventilation and compression, is based on a reconsideration of earlier data supporting simultaneous ventilation and compression and cardiopulmonary resuscitation (CPR) in adult humans and on evidence obtained in infant animals.

In adults, there is clear evidence that it is not direct compression of the heart, but a "thoracic pump" that plays a significant role in moving blood forward.[41] It was shown that in adults, simultaneous ventilation and compression and CPR increased aortic pressure and improved cerebral circulation.[10] Further work showed, however, that although cerebral circulation increased, myocardial blood flow diminished with simultaneous ventilation and compression and CPR.[43] In a controlled clinical trial looking at simultaneous ventilation and compression and CPR versus conventional ventilation in a prehospital setting, it became clear that simultaneous ventilation and compression and CPR offered no advantages, and the authors concluded that simultaneous ventilation and compression and CPR should not be used in the clinical setting.[27] Also, some laboratory data show no advantage to simultaneous ventilation and compression and CPR in infant pigs.[6]

In addition to the fact that simultaneous ventilation and compression offered no advantage in adult humans or newborn piglets, there are some potential limitations to simultaneous chest compression and ventilation in newborns. These include a compromised tidal volume; in a patient without an endotracheal tube in place, high airway pressures necessary to effect a tidal ventilation increase the amount of gas diverted into the stomach. A pressure monitor on the bag and mask would have limited value because it would be impossible to differentiate airway pressure associated with an adequate tidal volume from pressure associated with chest compression. Because ventilation is frequently administered with a self-inflating bag and mask, it would be necessary to override the pressure pop-off valve (usually set at 35 to 40 mm Hg), or the pressure generated would not be enough to deliver an adequate tidal volume.[32]

For all of these reasons, interposition of ventilation and compression is recommended: one ventilation interposed between every three compressions. The two clinicians performing these procedures should communicate by having the compressor count the cadence out loud as "one and two and three and breathe."[2] If chest compressions and ventilations do not increase the heart rate to greater than 60 beats/min within 30 seconds of well-coordinated chest compressions and ventilation, support of the cardiovascular system with medications is indicated.

MEDICATIONS

The use of medications is required when, despite ventilation and chest compression, the infant continues to have bradycardia, or when the infant is born with no detectable heartbeat. In the latter circumstance of the so-called apparent stillborn,[25] medications are started as soon as possible along with ventilation and chest compression. Medications should preferentially be given through an umbilical venous catheter. When an umbilical catheter is used, it should be inserted into the umbilical vein just beneath the skin, approximately 2 to 4 cm in a term infant. If the catheter is inserted too high and becomes wedged in the liver, solutions can be infused into the liver, which may cause liver necrosis. The depth of insertion of the catheter is much less in premature infants depending on their weight, and care should be taken not to insert the catheter too far. If a catheter is not prepared and ready, endotracheal administration of epinephrine may occur through the endotracheal tube while the catheter is being prepared. It is prudent, however, that when preparing for a "crash" delivery, the catheter should be prepared in advance to minimize the delay in giving epinephrine by the most effective route. Table 26-4 presents an overview of the various medications used in delivery room resuscitation, including concentration, dosage, route, and precautions.

Epinephrine

If PPV with oxygen and chest compression is unsuccessful in increasing the heart rate, use of medications is indicated. The first drug used should be epinephrine 1:10,000 (0.1 to 0.3 mL/kg intravenously). If necessary, the dose can be repeated every 3 to 5 minutes. Epinephrine has a beta$_1$-adrenergic effect, which stimulates the heart, but, more importantly, it also has an alpha-adrenergic effect that increases noncerebral peripheral resistance. By selective vasoconstriction of peripheral vascular beds, epinephrine increases cerebral and myocardial blood flow.[7] Although larger than recommended doses of epinephrine have been used in pediatric[20] and adult cases,[36] there is no information indicating an advantage of larger doses in neonates. On the contrary, data now indicate that there is higher mortality and morbidity when high-dose epinephrine is used.[38,56] High-dose epinephrine administration is not recommended via the intravenous route.[24]

If an intravenous route is not immediately available, epinephrine can be given through the endotracheal tube, but should be given at a higher dose than the standard intravenous dose (0.3 to 1 mL/kg).[2] Although low pulmonary blood flow associated with a resuscitation is still able to provide adequate plasma levels after endotracheal instillation of epinephrine,[29] other clinical data indicate that the standard intravenous dose of epinephrine is not effective when the dose is given through the endotracheal tube.[34,39,56] When giving epinephrine by endotracheal tube, it should be given directly into the tube followed by positive pressure breaths to distribute it throughout the lungs and maximize absorption.

There is an accumulating body of experimental evidence that the use of epinephrine may lead to myocardial damage. Berg and colleagues[4] in 1994 compared standard-dose epinephrine with high-dose epinephrine and were unable to show any improvement in 24-hour survival or neurologic outcome in the adult pigs in which high-dose epinephrine was used as part of a resuscitation. They noted, however, that most animals in the simultaneous ventilation and compression and CPR group exhibited a hyperadrenergic state that included severe hypertension and tachycardia.

Using an asphyxial model in young swine, Berg and colleagues[5] showed not only that a hyperadrenergic state existed in the animals given simultaneous ventilation and compression and CPR, but also that the mortality rate was significantly higher in these animals. In 1994, Ditchey and coworkers[16] used a beta-adrenergic blocker along with epinephrine and showed that there was a reduction in myocardial damage after CPR. This finding led to a series of studies indicating that when the beta-adrenergic effects of epinephrine are blocked, myocardial impairment after resuscitation is reduced. Myocardial impairment was also reduced when a selective alpha agonist, such as phenylephrine, was used.[44]

TABLE 26–4 Medications for Neonatal Resuscitation

Medication to Administer	Concentration	Preparation	Dosage; Route	WEIGHT OF INFANT/TOTAL DOSE			Rate; Precautions
				Weight (kg)		*Total mL*	
Epinephrine	1:10,000	1 mL	0.1-0.3 mL/kg; IV	1		0.1-0.3	Preferred route; give rapidly
				2		0.2-0.6	
				3		0.3-0.9	
				4		0.4-1.2	
			0.3-1 mL/kg; ET	1		0.3-1	3-10 times IV dose; give directly into ET tube
				2		0.6-2	
				3		0.9-3	
				4		1.2-4	
				Weight (kg)		*Total mL*	
Volume expanders	Normal saline solution, Ringer lactate solution, whole blood	40 mL	10 mL/kg; IV	1		10	Give over 5-10 min
				2		20	
				3		30	
				4		40	
				Weight (kg)	*Total Dose (mEq)*	*Total mL*	
Sodium bicarbonate	0.5 mEq/mL (4.2% solution)	20 mL or two 10-mL prefilled syringes	2 mEq/kg; IV	1	2	4	Give slowly, over at least 2 min Give only if infant is being effectively ventilated
				2	4	8	
				3	6	12	
				4	8	16	
				Weight (kg)	*Total Dose (mg)*	*Total mL*	
Naloxone hydrochloride	0.4 mg/mL	1 mL	0.1 mg/kg (0.25 mL/kg); IV, ET, IM, SQ	1	0.1	0.25	Give rapidly; IV, ET preferred, IM, SQ acceptable. Do not give if mother is suspected of narcotic addiction or on methadone maintenance (may result in severe seizures)
				2	0.2	0.50	
				3	0.3	0.75	
				4	0.4	1.00	
	1 mg/mL	1 mL	0.1 mg/kg (0.1 mL/kg); IV, ET, IM, SQ	1	0.1	0.1	
				2	0.2	0.2	
				3	0.3	0.3	
				4	0.4	0.4	
				Weight (kg)	*Total Dose μg/kg/min*		
Dopamine				1-4	5-20		Give as a continuous infusion, using an infusion pump. Monitor heart rate and blood pressure closely

ET, endotracheal; IM, intramuscular; IV intravenous; SQ subcutaneous.

The same group also showed the advantage of a pure alpha$_2$-adrenergic effect. The investigators blocked the alpha$_1$-adrenergic effect on the heart along with the beta-adrenergic effect of epinephrine, and showed an improvement in postresuscitation cardiac and neurologic recovery. They were able to confirm this advantage by using a selective alpha$_2$-adrenergic agent, alpha-methylnorepinephrine. Postresuscitation myocardial function and survival were significantly better in animals treated with alpha-methylnorepinephrine.[42] There is some reason to question epinephrine, with its alpha and beta effects, as the drug of choice in resuscitation and to consider the potential advantages of the use of a pure alpha$_2$-adrenergic agonist. Studies are yet to be done in neonates that would warrant any change in the current recommendations.

Volume Expanders

Although an asphyxiated infant may be in shock, this is not usually caused by hypovolemia, but by decreased myocardial function and decreased cardiac output. Most infants who have undergone intrauterine asphyxia are not hypovolemic. In some circumstances, however, hypovolemic shock is a real possibility (Box 26-5). Shock at birth may be caused by asphyxia, hypovolemia, or sepsis. In addition, most causes of hypovolemic and septic shock result in neonatal asphyxia. Most severely hypovolemic and septic infants are asphyxiated, but most septic or asphyxiated infants are not hypovolemic. Some studies have shown that antepartum asphyxia is associated with increased transfer of blood from the placenta to the fetus before birth, resulting in normal or increased circulating blood volume. The problem is in distinguishing hypovolemic and septic shock from asphyxial shock that does not involve hypovolemia.

A history of bright red vaginal bleeding just before delivery or the finding of a velamentous insertion of the umbilical cord or significant abruption at cesarean section raises the suspicion that there is acute fetal blood loss. Maternal fever, fetal tachycardia, and other signs of chorioamnionitis may indicate neonatal sepsis and shock. Volume expanders may be detrimental in an infant who is not hypovolemic, especially one who has experienced hypoxia-induced myocardial dysfunction. Volume expanders should be given in the acute circumstance when, after adequate ventilation and oxygenation have been established, poor capillary filling persists, and there is evidence or suspicion of blood loss with signs of hypovolemia. In an infant in whom the pulse cannot be normalized despite adequate resuscitation measures including epinephrine, volume expansion should be considered.

BOX 26–5 Causes of Hypovolemia

- Decreased blood return from placenta
- Cord compression resulting in venous, but not arterial occlusion
- Placental separation compromising placental blood return to the fetus
- Maternal hypotension
- Loss of blood from fetal-placental circulation (fetal to maternal hemorrhage)
- Hemorrhage from the fetal side of the placenta
- Fetal-fetal transfusion
- Incision of placenta during cesarean section
- Velamentous insertion of umbilical cord with fetal arterial rupture

If a pressure monitor and transducer are available in the delivery room, an umbilical arterial catheter may be used to obtain aortic blood pressure (see Appendix B, Tables of Normal Values). The use of a central venous line has been debated; a low central venous pressure in the presence of poor capillary filling and a low aortic pressure is good evidence of hypovolemic shock and requires volume expansion. To compound the problem in a hypovolemic infant, shock may not be evident at first in asphyxia. Early, there may be marked peripheral vasoconstriction, which maintains blood pressure. With an effective resuscitation, peripheral vasodilation occurs, and reperfusion acidosis ensues. At this point, a hypovolemic infant begins to manifest shock.

In an acute situation, the volume expander of choice is normal saline; 5% albumin has been used, but offers no advantage over crystalloid solutions. In a randomized study of infants with low birthweight with hypotension, saline was compared with 5% albumin. No differences were noted in the number of infants who went on to receive pressor support. Infants given albumin had significantly more weight gain in the first 48 hours, however, than infants given normal saline. This increase in weight may be because albumin easily crosses capillary walls into the extravascular space, reducing the oncotic pressure difference between the vascular space and the interstitium, and making fluid retention more likely.[18] Another study comparing albumin with crystalloid showed an increased mortality in the albumin group. Albumin infusion also carries the risk of transmission of infectious diseases.[33] If time permits, fresh frozen plasma can be used. The best volume expander, although rarely available, is whole O-negative blood crossmatched against the mother's blood; this provides volume, oxygen-carrying capacity, and colloid.

In an emergency situation, blood can be withdrawn from the fetal side of the placenta and infused into the infant. Although this should very rarely be necessary, if it must be done, it should be performed in a sterile manner as soon as possible after the placenta is delivered. The syringe used to withdraw the blood should be heparinized, and a filter should be attached to the syringe so that microclots can be filtered out before entering the syringe. Before the blood is infused into the infant, the filter should be changed, and blood should be passed through the filter a second time during the infusion. Infusion of volume expanders should consist of a volume of 10 mL/kg given over 5 to 10 minutes. In true acute hypovolemia, it is often necessary to repeat this infusion a second or third time. Delay in clamping or milking of the cord is desirable in certain circumstances.

Sodium Bicarbonate

The use of sodium bicarbonate has been discouraged by the NRP during the acute phase of a neonatal resuscitation in the delivery room.[2,56] Despite significant evidence that the administration of bicarbonate does not affect outcomes, however, the United Kingdom Resuscitation Council continues to recommend sodium bicarbonate during the early phases of resuscitation, especially when severe metabolic acidosis is suspected or proven by arterial blood gases.[40] In the United Kingdom, sodium bicarbonate is mentioned with the same importance as epinephrine and recommended to be given before administering the second dose of epinephrine.

An asphyxiated infant may have both respiratory and metabolic acidosis. Adequate ventilation corrects the respiratory acidosis. The establishment of adequate circulation and oxygenation, along with sufficient carbohydrates for fuel, stops progression of the acidosis, results in metabolism of lactic acid, and clears the remaining acidosis. (See also Chapter 36.) There may be instances in a prolonged resuscitation when it seems reasonable to use sodium bicarbonate, although some researchers believe it is "basically useless therapy."[3] If bicarbonate is given, it should be done only after adequate ventilation is established.

In the absence of adequate ventilation, the administration of bicarbonate may be harmful. Bicarbonate administration results in an acute increase in carbon dioxide. The carbon dioxide crosses cell membranes quickly and lowers the pH of all major organs, including the heart and brain[8]; this can be attenuated with adequate ventilation. Before bicarbonate is administered, one must be certain that adequate ventilation is established. Another potential danger associated with the use of acute doses of bicarbonate is intracranial hemorrhage, especially in a preterm infant.[35]

The 2005 AHA guidelines for CPR recommended against the use of *any* buffers during cardiac arrest.[17] These guidelines cite the lack of improved outcomes with the use of buffers and the potential adverse effects, including compromise of coronary perfusion by reducing systemic vascular resistance, creating extracellular acidosis, shifting the oxyhemoglobin curve and inhibiting oxygen release, producing hyperosmolarity and hypernatremia, producing excess carbon dioxide, and exacerbating central venous acidosis. If sodium bicarbonate is required after a prolonged resuscitation, the recommended dose is 2 mEq/kg.[2] To avoid a sudden increase in osmolality, with the risk of intracerebral hemorrhage, the concentration of bicarbonate should be 0.5 mEq/mL, infused at a rate of no more than 1 mEq/kg per minute; it should take at least 2 minutes to infuse the entire dose, and many clinicians advise giving it much more slowly.

Dopamine

Sometimes an infant has experienced enough myocardial compromise that, despite all resuscitative measures, poor cardiac output and hypotension remain. If the infant is not hypovolemic, inotropic support is indicated, rather than continued volume expansion in the face of hypoxic cardiomyopathy. In these circumstances, dopamine may be used. At dosages of 10 μg/kg per minute, dopamine has an inotropic effect and an alpha-adrenergic effect. At these dosages, the increased cardiac output antagonizes the alpha-adrenergic effect, however, resulting in increased cardiac output with only mild peripheral vasoconstriction. In higher doses, the alpha-adrenergic effect predominates with generalized peripheral vasoconstriction. In low doses of 5 μg/kg, dopamine binds to dopaminergic receptors in the renal, mesenteric, and cerebral arteries, producing vasodilation. Traditionally, dopamine is started at 5 μg/kg per minute, and the dosage is increased as necessary. There is some evidence, however, that the neonate may respond to initial doses that are much smaller than the doses commonly recommended. If the dosage reaches 20 μg/kg per minute of dopamine without adequate response, it is unlikely that increasing the dose further would make a difference.

DRUG-DEPRESSED INFANT

Respiratory depression is common if a mother has been given a narcotic analgesic within 4 hours of delivery or an inhalation anesthetic before a cesarean section. If the depression is solely related to the drug, with no overlying asphyxia, the infant usually has a good heart rate and simply needs ventilation. If the problem is caused by an inhalation anesthetic, ventilation of the infant usually removes the anesthetic from the infant's circulation. If the cause of the respiratory depression is due to administration of a narcotic to the mother within 4 hours of delivery, naloxone (Narcan) may be useful in antagonizing the respiratory depressant effect. The dose is 0.1 mg/kg.[2]

The preferred route of administration of naloxone is intravenously through an umbilical catheter. Naloxone can be given intramuscularly, but the onset of action is delayed because the drug needs to be absorbed from the injection site. There are no studies reporting the efficacy of naloxone given via the endotracheal tube, and this route is not recommended.[2,24] Naloxone does not reverse the effects of inhalation anesthetics. Naloxone is *not* the first drug given in a resuscitation and should rarely, if ever, be used in the delivery room.[23] When an infant has been stabilized and has achieved good acid-base status, but remains hypotonic and has the appropriate history, naloxone may be indicated. The duration of action of the narcotic may be longer than the duration of action of naloxone. The naloxone may wear off before the narcotic, and the infant may slip back into respiratory depression. Repeated doses of naloxone may be necessary. Naloxone should never be given to an infant of a narcotic-addicted mother because the infant may have acute withdrawal symptoms, including seizures.

IMMEDIATE CARE AFTER ESTABLISHING ADEQUATE VENTILATION AND CIRCULATION

When an infant is stabilized after resuscitation, the next steps require deliberate consideration. The future course of the infant's resuscitation is related to how well the lungs function and to the presence or absence of a good respiratory drive. Many infants improve rapidly, quickly attaining good lung compliance, adequate pulmonary blood flow, and spontaneous respiration. In these infants, resuscitative efforts can be withdrawn within minutes. Attention must be paid to the amount of assisted ventilation needed as the infant is improving. As compliance improves, there is a tendency to overventilate the infant's lungs. In one study of preterm infants requiring resuscitation in the delivery room, 26% had unintended hypocarbia on NICU admission.[48] In addition, if oxygen was needed, the amount of oxygen can often be reduced to avoid hyperoxia.

The use of a pulse oximeter in the delivery room facilitates the maintenance of targeted $\mathrm{Sp{O_2}}$; this is especially important in preterm infants. A term or near-term infant who has been successfully resuscitated and is now vigorous may present a dilemma in determining to which level of care he or she should be admitted. The NRP algorithm indicates that infants who receive PPV should be monitored in a nursery that has "postresuscitation care." This means an infant should not be sent to a well-baby nursery or allowed to go to the mother's room without monitoring until the infant can be assessed for a reasonable period. In a small study of term infants, the authors showed that infants who had received PPV in the delivery room and were then sent to well-baby care had a 52% chance of later being transferred to the NICU.[19]

Prolonged Assisted Ventilation

Some infants need a ventilator after immediate resuscitation. In a severely asphyxiated infant, CNS depression may inhibit spontaneous ventilation. As pointed out earlier, the longer the asphyxia lasts, the longer it takes for resumption of spontaneous ventilation. Most infants in this category also have some degree of pulmonary compromise related to asphyxia. Some infants with primary lung disease initially breathe spontaneously; however, these infants subsequently may need assisted ventilation to attain adequate blood gases. Asphyxia may also affect the type 2 cells of the lung and result in acquired surfactant deficiency. Meconium, blood, or sepsis may also deactivate surfactant resulting in the need for continued ventilatory support. Whenever an infant is in need of ventilation for more than the immediate resuscitative period, evaluation of blood gases should guide the ventilatory support. Prolonged hand ventilation is often overzealous or inadequate. Continued ventilation by machine or a T-piece resuscitator gives more uniform ventilation. (See also Chapter 44, Part 4.)

Glucose

As soon as hypoxia is corrected, an infusion of glucose at approximately 4 to 8 mg/kg per minute should be started. Adjustment of the glucose infusion rate depends on repeated measurements of blood glucose levels. The purpose of the glucose is twofold: (1) to provide fuel and (2) to help eliminate the metabolic acidosis. A steady infusion of glucose provides fuel to an infant who has depleted much of his or her glycogen, especially myocardial glycogen, during the asphyxial episode. This infusion helps prevent the hypoglycemia that frequently accompanies asphyxia. Glucose should not be started until the infant is adequately oxygenated. Anaerobic metabolism of carbohydrate leads to the formation of additional lactic acid, worsening the acidosis. Hypoglycemia is synergistic with asphyxia in producing brain damage, and failure to provide glucose and monitor levels may result in additional brain injury.[9,24]

Fluids

The urine output of any infant undergoing an asphyxial episode should be carefully monitored. Acute tubular necrosis resulting in oliguria is a common complication of asphyxia, and an infant can easily be overloaded with fluid. Fluid should be restricted until there is evidence of adequate urine output. The need to restrict fluid and yet give glucose emphasizes the importance of considering glucose infusion in terms of milligrams of glucose per kilogram of body weight per minute, rather than the amount of 10% glucose to be given. The concentration of infused glucose depends on how much fluid can be given to the infant. (See also Chapter 36.) In addition, the potentially nephrotoxic antibiotics and diuretics should be administered with caution because poor renal clearance may result in toxic levels.

Feeding

During asphyxia, ischemia of the intestine occurs as a result of vasoconstriction of the mesenteric vessels. Because of the suggested relationship between ischemia of the intestine and necrotizing enterocolitis, it may be prudent to delay enteral feedings in an asphyxiated infant, especially one who is premature. (See also Chapters 35 and 47, Part 4.)

Other Problems

Other complications of asphyxia that are of concern include hypocalcemia, disseminated intravascular coagulation, seizures, cerebral edema, and intracerebral hemorrhage. These are discussed elsewhere in this text.

SPECIAL PROBLEMS DURING RESUSCITATION

Infants with Very Low Birthweight and Extremely Premature Infants

Infants born at less than 32 weeks' gestation or less than 1500 g birthweight require special considerations in the delivery room. Most facilities do not have an adjacent NICU to provide a warm and monitored environment immediately for these very fragile infants, so provisions must be made in the delivery room. It has been suggested that simulating the intensive care environment in the delivery room from the moment of birth helps to improve survival and reduce morbidity in this population.[51] The provision of a well-trained and complete resuscitation team at delivery is of paramount importance. Temperature control and warming techniques to prevent hypothermia are often difficult to achieve because of the physical characteristics of the premature newborn. The use of a polyethelene occlusive wrap and the warming of the delivery room to 25°C (77°F) are essential to maintaining the core temperature.[52]

NRP recommends the use of pulse oximetry and blending oxygen in the delivery room to avoid hyperoxia.[2] The avoidance of barovolutrauma during initial ventilatory support may be facilitated by the use of a T-piece resuscitator, the use of an end-tidal CO_2 detector, and the measurement of tidal volumes. The early administration of surfactant, especially in infants who are suspected by history to be deficient, may also reduce long-term respiratory morbidity. Many infants may be managed with an *INSURE* protocol (*IN*tubation, *SUR*factant, *E*xtubation) or placed directly on nasal CPAP without intubation.

Meconium Aspiration

If meconium is present in the amniotic fluid, there is a chance that meconium may enter the mouth of the fetus and be aspirated into the lungs. Aspiration of meconium can result in a ball-valve obstruction of the airways, causing gas trapping and pneumothorax. It can also cause a reactive inflammatory process. Because meconium-stained amniotic fluid is frequently associated with asphyxia in newborns, the inability to effect adequate ventilation combined with the initial asphyxia may result in enough hypoxia and acidosis to maintain the increased resistance of the pulmonary vasculature resulting in persistent pulmonary hypertension of the newborn.

During the last several decades, the management of an infant born through meconium has represented a controversial area with changing recommendations. Vain and colleagues[50] showed that suctioning the hypopharynx after delivery of the head and before delivery of the shoulders has no effect on the development of meconium aspiration syndrome. NRP has withdrawn the recommendation to perform this procedure at birth. The recommendations for care of a meconium-stained infant after birth have also been revised in recent years and continue to be examined. The hallmark study of Gregory and associates[22] in 1974, done before suctioning on the perineum was common, recommended that "all infants born through thick, particulate, or pea soup meconium should have the trachea aspirated immediately after birth." This recommendation was reinforced in a retrospective, uncontrolled study by Ting and coworkers[45] in 1975, in which vigorous infants with slight meconium were excluded. As a result of the Gregory and Ting studies and a 1977 statement by the AAP Committee on Fetus and Newborn, which said nothing about suctioning the hypopharynx on the perineum, intubation and tracheal suctioning became routine in many delivery rooms.

In the 1980s, there were reports in the obstetrics literature that meconium aspiration syndrome continued to occur even with "appropriate" management of the infant.[14] In the neonatal resuscitation guidelines of 1986,[31] it was suggested that all infants with thick meconium should undergo intubation and tracheal suction. No distinction was made with regard to depressed versus vigorous infants. In 1988, Linder and colleagues[28] published a controlled, randomized trial examining the value of endotracheal intubation and suction in vigorous infants. They noted that in vigorous infants the morbidity rate, including complications of intubation, was 2% greater in infants who had undergone intubation and suctioning. In 1990, Cunningham and associates[11] proposed a standard of care that reserved intubation largely for infants who were depressed and who required PPV.

In 1992, the AAP/American College of Obstetricians and Gynecologists Guidelines for Perinatal Care recommended that, in the presence of thick meconium and respiratory depression, the larynx be visualized, and if meconium is seen, the trachea be intubated and suctioned. It was noted that if the infant is vigorous, the indication for visualization of the cords and endotracheal suction is "less clear." In an article reporting a retrospective chart review in 1992, Wiswell and coworkers[54] argued that endotracheal intubation should not be limited to depressed infants because 54% of their study infants with meconium aspiration syndrome did not need PPV and were presumed vigorous at birth, including one infant with only thin meconium. Wiswell and coworkers[54] also noted no significant adverse sequelae associated with intubation.

In 2000, a multicenter study looked at vigorous infants with a gestational age of more than 37 weeks who were born through meconium-stained amniotic fluid of any consistency. In these vigorous infants, intubation and tracheal suctioning did not offer any advantage over expectant management.[53]

The present recommendations[1] are that all depressed infants, with either thick or thin meconium, should undergo direct tracheal suctioning. It seems that vigorous infants, regardless of the thickness of the meconium in the amniotic fluid, need not be handled in a special way. Although clinical judgment should be used to determine if the infant is vigorous, studies are now under way to determine if prophylactic suctioning of any meconium-stained infants would improve outcome. Many clinicians believe that meconium aspiration syndrome is an intrauterine phenomenon secondary to fetal gasping in an acidotic state, and that suctioning the trachea should be done only if the infant requires PPV or intubation for PPV. The results of ongoing studies are awaited before further recommendations can be made.

If intubation is to be done and meconium removed from the trachea, the best method is to attach an adapter to the endotracheal tube so that suction can be directly applied using regulated wall suction at approximately 100 mm Hg as the tube is withdrawn. The trachea can be reintubated and suctioned again if necessary. Because some infants with thick meconium are severely asphyxiated, it may be impossible to clear the trachea completely before beginning PPV. Clinical judgment determines the number of reintubations necessary and appropriate to the condition of the infant. (See also Chapter 44, Part 5.)

Pneumothorax

A pneumothorax may occur spontaneously and may be the cause of the need for resuscitation. More commonly, pneumothorax is a complication of PPV. Pneumothorax should be suspected in any infant who is improving during a resuscitative effort and then suddenly decompensates. Listening to the infant, one may hear unequal breath sounds and distant heart sounds, which may be shifted from the normal position in the left side of the chest. The affected side of the chest may appear hyperinflated compared with the nonaffected side, and has less movement during ventilation. If the pneumothorax is large enough to obstruct venous return, cardiac output decreases, and the infant becomes hypotensive and eventually bradycardic. When these events occur in an infant who is otherwise stable, pneumothorax is easy to suspect. When pneumothorax occurs early during resuscitation of a severely compromised infant, however, the signs and symptoms are not as obvious. When immediate intervention in the delivery room is needed, it may be necessary to insert a needle into the thorax before radiographic confirmation. The NRP textbook suggests using an 18-gauge or 20-gauge percutaneous catheter and inserting it in the fourth intercostal space in the anterior axillary line.[2] (See also Chapter 44, Part 5.)

Congenital Diaphragmatic Hernia

With the increasing availability of prenatal ultrasound, most infants with congenital diaphragmatic hernia (CDH) are anticipated and can be delivered in a level III center where the appropriate team can attend the delivery. An infant with an undiagnosed CDH is usually in significant respiratory distress at birth, and the diagnosis may not be immediately obvious. The diagnosis may be suspected when there is a scaphoid abdomen and decreased breath sounds, usually on the left side (85%). The situation may be worsened by the use of mask ventilation, which inflates the bowel in the chest and compromises ventilation further.

An infant with CDH may appear similar to an infant with a pneumothorax. To prevent gas from entering the intestines, one should always use an endotracheal tube when ventilating the lungs of an infant with a suspected CDH. An orogastric tube should be inserted as soon as possible to remove air before it passes into the portion of intestine located in the chest. Some clinicians also use a paralyzing agent to ablate spontaneous respirations and prevent air from entering the intestines. (See also Chapters 11; 44, Part 5; and 47, Part 3.)

Erythroblastosis and Hydrops Fetalis

Successful resuscitation of an infant with hydrops demands preparation of a coordinated team with preassigned responsibilities. The team should be prepared at delivery to perform a partial (or, rarely, complete) exchange transfusion with O-negative packed cells crossmatched against the mother. In addition, they should be prepared to perform a thoracentesis, paracentesis, and complete resuscitation. In recent years, most infants with hydrops have nonimmune causes. With advanced ultrasound technology, most of these infants are diagnosed in utero, and the delivery and resuscitation can be carefully planned. An infant with hydrops may not only be severely anemic, but also is likely to have ascites, pleural effusions, and pulmonary edema. Such infants frequently have had chronic intrauterine and intrapartum asphyxia. Because they are usually premature, respiratory distress syndrome may be an underlying confounding complication.

On delivery, the infant should immediately undergo intubation because of poor lung compliance and the risk of pulmonary edema. High ventilator pressures are typically needed and the use of high frequency ventilation may be necessary to minimize lung injury. If adequate ventilation cannot be attained, and there is evidence of fluid in the abdomen or pleural space, consideration should be given to performing a paracentesis and a thoracentesis. Ultrasonography performed before delivery may be helpful in determining in which spaces the fluid resides (pleural, ascitic, or pericardial) and the amount of fluid present. If the abdomen is markedly distended, the paracentesis should be performed first to relieve pressure on the diaphragm; this may need to be followed with a thoracentesis. Although most of these infants initially have a normal blood volume, after a large amount of ascitic and pleural fluid has been removed, some of this fluid may reaccumulate, reducing intravascular volume. Careful attention should be paid to maintenance of intravascular volume and the prevention of shock after resuscitation.

A hematocrit obtained immediately at birth determines the need for an exchange transfusion (usually partial) in the delivery room. If the infant is extremely anemic and in need of oxygen-carrying capacity, catheters should be inserted into the umbilical vein and artery to permit a slow isovolemic exchange with packed cells, which results in minimal impact on the already borderline hemodynamic status of the infant. These lines also can be used to monitor central venous pressure and aortic pressure to determine the volume needs of the infant. This is especially important when large amounts of fluid are removed from the thorax or abdomen. Given the complexity of the resuscitation in these cases, the resuscitation team must be of sufficient number and skill to perform these procedures expeditiously and skillfully to achieve optimal outcome.[21](See also Chapters 21, 22, and 46.)

SCREENING FOR CONGENITAL DEFECTS

Two percent to 3% of infants are born with a congenital anomaly that requires intervention soon after birth. (See also Chapters 27 and 29.) If undetected, some of the anomalies may result in life-threatening problems. Immediately after birth, choanal atresia or CDH may result in respiratory distress. Other problems may appear later, such as aspiration caused by esophageal atresia (with esophageal fistula) or a high intestinal obstruction. A rapid screening test for congenital defects that can easily be performed by the delivery room staff can help identify many of these defects, along with others that are not life-threatening but require prompt recognition and intervention.

Before examining the infant, the team should inquire about the amniotic fluid, placenta, and umbilical cord. Oligohydramnios may be a marker for oligohydramnios sequence or Potter syndrome with pulmonary hypoplasia.[47] These infants also have growth deficiency, Potter facies, and limb positional defects. A significantly short umbilical cord at term (<40 cm) is a sign of fetal akinesia sequence and usually indicates a muscle or CNS etiology for the infant's respiratory insufficiency, or may be associated with pulmonary hypoplasia (Pena-Shokeir syndrome).[30]

Physical Examination

A rapid external physical examination identifies obvious abnormalities, such as abnormal facies and limb, abdominal wall, or spinal column defects. A close look at the abdomen may reveal a scaphoid abdomen, which is a clue to a CDH. If an umbilical vessel count reveals only two vessels, there is a possibility of other defects, especially involving the genitourinary tract. Because infants are preferential nasal breathers, bilateral choanal atresia results in respiratory difficulty and requires an oral airway at birth. (See also Chapter 44, Parts 5 and 6). Bilateral choanal atresia can be ruled out quickly if the infant is able to breathe while the mouth is held closed. Some infants with unilateral choanal obstruction appear normal until an examiner closes the mouth and then sequentially obstructs each nostril with a finger. When the patent nostril is obstructed, such infants have difficulty breathing. Choanal atresia is confirmed by the insertion of a soft nasogastric tube into each nostril. If an obstruction is reached within 3 to 4 cm, choanal atresia is a possibility.

An examination of the mouth may identify a cleft palate. Inserting a nasogastric tube through the mouth may help identify an esophageal atresia or a high intestinal obstruction. If the tube does not reach the stomach, an esophageal atresia, most often associated with a tracheoesophageal fistula, is likely. A few cubic centimeters of air forced through the tube, while listening over the stomach, confirms that the tube is in the stomach. When the tube is in the stomach, the contents of the stomach can be suctioned. It is not recommended, however, that the stomach routinely be emptied of its contents at birth. If more than 15 to 20 mL of gastric contents are obtained, the chances of a high intestinal obstruction are increased. The same tube can be removed and gently inserted into the anal opening. Easy passage of the catheter for 3 cm into the anus makes atresia unlikely. A minute or so spent screening for congenital defects in this way may help to avert many future problems.

CHAPTER 27

Physical Examination of the Newborn

Tom Lissauer

Immediately after a baby is born, all parents want to know, "Is my baby all right?" A quick initial physical examination of all newborns should be performed in the delivery room to ensure that there are no major anomalies or birth injuries, that the newborn's tongue and body appear pink, and that breathing is normal. The entire body must be checked. This usually allows the clinician to reassure the parents that their infant looks well and appears normal.

Many serious congenital anomalies will have been identified prenatally, their presence anticipated, and a management plan made before delivery. If the newborn is sufficiently preterm or small for gestational age, has a significant problem diagnosed prenatally, or is unwell (e.g., with respiratory distress), the newborn must be admitted to an intermediate or intensive care nursery in accordance with hospital guidelines. If the mother had severe polyhydramnios, a feeding tube should be passed into the infant's stomach to exclude esophageal atresia. When the infant is born, the parents will have been informed if it is a boy or girl. If there is any doubt about the infant's gender, it is important not to guess but to inform the parents that further evaluation is required before a definite decision is made.

During the first few hours after birth, healthy newborns are usually alert and reactive and will suck at the breast. This behavior provides an initial opportunity for the mother to form a close attachment with her infant and to establish breast feeding. Medical interference during this time should be kept to a minimum.

ROUTINE EXAMINATION

Every newborn infant should undergo a "routine examination of the newborn."[2,24] This is a detailed examination performed by an experienced health care provider within 24 hours of birth. The objectives of the examination are listed in Box 27-1. The routine examination is described later, followed by a description of some conditions that resolve spontaneously and some of the significant abnormalities that may be encountered. Detailed descriptions of these abnormalities are found elsewhere in the book.

Preparation

Before approaching the mother and infant, the mother's and infant's medical and nursing records should be checked. Relevant items are listed in Box 27-2.

Introduction to the Mother

The health care provider should introduce himself or herself to the mother or, preferably, to both parents and explain the purpose of the examination. It is usually best at this stage to inquire whether there are any problems with feeding and any other worries about the infant. Before starting the examination, the health care professional must observe hand hygiene and ensure that the newborn can be examined in a warm, private area with good lighting.

Order of the Examination

The exact sequence in which the newborn is examined is not important. What is important is that all aspects of the newborn are examined at some stage and that the entire infant is observed. If the newborn is quiet, one may well take the opportunity to listen to the heart and examine the eyes directly. It is often convenient to make one's general observations of the newborn's appearance, posture, and movements while undressing him or her, then to conduct the examination from head to foot, to examine the hips, and finally to pick the newborn up and turn him or her over to examine the back (Fig. 27-1). A checklist is helpful to record the findings of the examination and to ensure that nothing has been omitted.

BOX 27–1 **Objectives of Routine Examination of the Newborn**

Detect congenital abnormalities not already identified at birth (e.g., congenital heart disease and developmental dysplasia of the hip).

Determine whether any of the wide range of nonacute neonatal problems are present and initiate their management or reassure the parents.

Check for potential problems arising from maternal disease, familial disorders, or problems detected during pregnancy.

Provide an opportunity for the parents to discuss any questions about their infant.

Initiate health promotion for the newborn.

BOX 27–2 **Mother's and Infant's Records**

Items of particular relevance in the mother's and infant's medical and nursing records are

- Maternal age, occupation, and social background
- Family history of medical problems
- History of maternal drug or alcohol abuse, socially high-risk circumstances (e.g., maternal psychiatric disease, domestic violence, child protection issues, unsatisfactory home conditions)
- Details of previous pregnancies and any medical problems experienced by those children
- History of maternal disease and medication taken during pregnancy
- Results of pregnancy screening tests (e.g., blood tests including maternal syphilis and hepatitis B surface antigen, prenatal ultrasound scans)
- Results of special diagnostic procedures (e.g., amniocentesis, chorionic villus sampling)
- Problems during labor and delivery
- Infant's condition at birth and if resuscitation was required
- Any concerns about the infant from nursing staff or parents
- The infant's birthweight
- The gestational age and if there is any uncertainty about it
- The infant's gender

Measurements

The infant's birthweight, gender, and gestational age should be noted. The 10th to 90th percentile for weight at 40 weeks' gestation for a male infant is 2.9 to 4.2 kg (mean, 3.6 kg) and for a female infant is 2.8 to 4 kg (mean, 3.5 kg; see Appendix). The birthweight percentile should be ascertained from the gestation-specific growth chart. If the infant's gestational age is uncertain, it can be determined (±2 weeks' gestational age) using a standardized scoring scheme.

The head circumference should be measured with a disposable tape measure at its maximal occipital frontal circumference and plotted on a gestation-specific growth chart to identify microcephaly or macrocephaly and to serve as a reference for future measurements. However, the measurement can change markedly in the first few days because of molding of the head during delivery. The 10th to 90th percentile is 33 to 37 cm at 40 weeks.

The infant's length (48 to 53 cm at 40 weeks) is measured routinely in the United States. Because the hips and lower legs need to be held extended by an assistant, the length is rarely measured accurately enough to identify short stature or serve as a reliable reference value when measured routinely.[24] The length of the arms and legs relative to that of the trunk is observed, although short limbs from skeletal dysplasias can be difficult to appreciate in the immediate newborn period.

General Observation of Appearance, Posture, and Movements

Much valuable information can be gleaned by simply observing the newborn. The skin of a newborn looks reddish pink. He or she may appear plethoric from polycythemia or unduly pale from anemia or shock. If polycythemia or anemia is suggested, the hemoglobin concentration or hematocrit should be checked. Jaundice within the first 24 hours of birth, unless mild, is most likely to be hemolytic and requires investigation and treatment.

Central cyanosis is best observed on the tongue. If present, it requires urgent investigation. If there is any doubt, the newborn's oxygen saturation should be checked with a pulse oximeter. Polycythemic infants sometimes appear cyanotic because they have more than 5 g of reduced hemoglobin per 100 mL of blood, even though they are adequately oxygenated.

The facial appearance is observed. If the face is abnormal, does the newborn have a syndrome? Observe the newborn's posture and tone. Is he or she moving all four limbs fully and are they held in a normal, flexed position?

Head

The shape of the head should be noted. It may be asymmetric from the infant's intrauterine position or molding during delivery. After elective cesarean birth, the infant's head shape is round and symmetric. The fontanelle and sutures are palpated. The size of the anterior fontanelle is variable. After delivery, the sagittal suture is often separated, and the coronal sutures are overriding. The posterior fontanelle is often open, but small. If the fontanelle is tense when the newborn is not crying, this may be from elevated intracranial pressure, and cranial ultrasonography should be performed. A tense fontanelle is also a late sign of meningitis.

Eyes

The eyes should be checked both by inspection and with an ophthalmoscope. The size, slant, and position of the eyes should be noted. The red reflex should be elicited using an ophthalmoscope held about 18 inches from the infant's eyes and focused on the pupil. The red retinal reflex can be seen if the lens is clear but not if it is opaque from a congenital

cataract or glaucoma. If the red reflex is abnormal, an ophthalmologist should be consulted urgently. Congenital cataract is the most common form of preventable childhood blindness. A white pupillary reflex (leukocoria) is an important presentation of retinoblastoma.

Ears

The shape, size, and position of the ears are checked. Low-set ears are positioned so that the top of the pinna falls below a line drawn from the outer canthus of the eye at right angles to the face. Low-set or abnormal ears are characteristic of a number of syndromes.

Mouth and Palate

The mouth is observed for size, position, and asymmetry. The palate must be inspected, including posteriorly, to exclude a posterior cleft palate. It should also be palpated to detect an indentation of the posterior palate from a submucous cleft or a posterior cleft palate.

Breathing

Breathing and chest wall movement are observed. The respiratory rate should be less than 60 breaths per minute without chest retraction, flaring of the alae nasi, or grunting (i.e., no signs of respiratory distress). If the breathing is normal, it is rare for significant abnormalities to be detected on auscultation. If the infant has respiratory distress, further evaluation is required immediately.

Heart

The normal heart rate is 110 to 150 beats per minute in term infants but can drop to 85 beats per minute during sleep. The heart sounds should be loudest on the left side of the chest, and no murmurs should be present.

Abdomen

Observe for abdominal distention, asymmetry, and signs of umbilical inflammation. For abdominal palpation, the infant must be relaxed. The abdomen is palpated to identify any masses. The liver is normally palpable 1 to 2 cm below the costal margin. The spleen tip and left kidney are sometimes palpable; assess for enlargement. Observe for a hernia in the inguinal canal.

Femoral Pulses

Femoral pulses are palpated when the infant is quiet. Pulse pressure is reduced if there is coarctation of the aorta. If coarctation is suggested clinically, it can be confirmed by comparing the blood pressure in the arms and legs. Pulse pressure is increased with a patent ductus arteriosus.

Genitalia

In boys, the penis is checked for length and the position of the urethral orifice. The presence of testes in the scrotum is confirmed, especially if the scrotum is poorly developed. In girls, the clitoris and labia minora are prominent if the infant is preterm but are covered by the labia majora at full term. The position and appearance of the anus is also inspected. Passage of urine and meconium should be monitored and recorded.

Extremities

The hands and arms and the feet and legs are examined to identify any abnormality such as extra digits (polydactyly), fused digits (syndactyly), or shortened digits (clinodactyly). Whereas unilateral single palmar transverse creases are observed in about 4% of infants, bilateral single palmar transverse creases occur in less than 1% of infants and are a clinical feature in infants with trisomy 21.

Infants who were in an extended breech position in utero sometimes maintain this posture for some days after birth.

Hips

The hips are checked for developmental dysplasia of the hip (DDH). It is best left toward the end of the examination because the procedure is uncomfortable. To successfully perform this examination, the infant must lie supine on a flat, firm surface and be relaxed because crying or kicking results in tightening of the muscles around the hip.

The pelvis is stabilized with one hand. With the other hand the examiner's middle finger is placed over the greater trochanter and the thumb placed along the middle thigh. The Barlow test is performed to posteriorly dislocate an unstable hip that is lying in the joint (see Chapter 54, Part 3). The hip is flexed to 90 degrees and adducted, and the femoral head is gently pushed downward. If the hip can be dislocated, the femoral head will be pushed posteriorly out of the acetabulum and will move with a clunk.

Next, the hip is checked to see if it can be returned from a dislocated position back into the acetabulum (the Ortolani test; see Chapter 54, Part 3). The hip is abducted, and upward leverage is applied. A dislocated hip will return with a clunk into the acetabulum. This is best felt but can sometimes also be observed. Little force is required for these procedures; excessive force can damage the hip. During the test, clicks might be elicited but are not of long-term consequence. It should also be possible to abduct the hips fully; limitation of abduction may be due to a dislocated hip. Other signs are asymmetry of the thigh or gluteal folds and apparent leg length shortening. Any newborn with DDH should be checked for a neuromuscular disorder, and the spine should be examined to exclude spina bifida.

Back, Spine, and Muscle Tone

The newborn is picked up under the arms while supporting the head. A hypotonic newborn will feel as though he or she is slipping through one's hands. Most newborns support their weight with their feet. When an infant is turned prone, the infant can lift the head to the horizontal and straighten the back. Hypotonic newborns flop down like a rag doll. The entire back and spine are checked for midline and other defects and for curvature of the spine.

A detailed neurologic examination is only required if an abnormality has been detected. Some pediatricians routinely elicit a Moro reflex, during which sudden head extension causes symmetric extension followed by flexion of all limbs. However, if normal movement of all four limbs has been observed, no further information will be gained from this procedure. Because infants appear to find it unpleasant and parents are often alarmed and upset by it, the Moro reflex test is best omitted from the routine examination.

Most newborns are found to be normal on routine examination. The parents should be strongly reassured that the examination was normal, and any concerns they have about their newborn should be addressed fully.

CONDITIONS THAT RESOLVE SPONTANEOUSLY

A number of conditions that could be observed during the routine examination might alarm parents but resolve spontaneously.

Peripheral and Traumatic Cyanosis

Peripheral cyanosis confined to the hands and feet is common during the first day of life and is of no clinical significance.

Traumatic cyanosis is blue discoloration of the skin, often with petechiae. It can affect the presenting part in a face or breech presentation or the head and neck if the umbilical cord was wrapped around the infant's neck. However, the tongue remains pink.

Bruising of the Head

The head can be markedly molded from having to squeeze through the birth canal. Newborns who have been in the breech position in utero often have a prominent occipital shelf. A caput succedaneum is bruising and edema of the presenting part of the head. It extends beyond the margins of the skull bones. A cephalhematoma is caused by bleeding between the periosteum and the skull bone. It is confined within the margins of the skull sutures and usually affects the parietal bone. Bruising and abrasions after forceps deliveries, from scalp electrodes, or from fetal blood sampling are relatively common (see Chapter 28).

Swollen Eyelids

Swelling of the eyelids is common in newborns and resolves during the first few days of life. There may also be a mucoid discharge, often called a "sticky eye." When present on the first day of life, it usually resolves spontaneously. The eyelids can be cleansed with sterile water.

This condition must be contrasted with the erythematous, swollen eyelids with purulent eye discharge seen in conjunctivitis in the first day of life from gonococcal infection, which is rare in developed countries. In the United States, all infants are given eye drops as prophylaxis against gonococcal conjunctivitis.

Subconjunctival Hemorrhages

Subconjunctival hemorrhages are common. They occur during delivery and resolve in 1 to 2 weeks.

Dry, Peeling Skin

Dry skin is common, especially in post-term infants.

Capillary Hemangioma (Stork Bites)

Capillary hemangiomas are pink macules appearing on the upper eyelids, the mid forehead, and the nape of the neck from distention of dermal capillaries. Those on the eyelids and forehead fade during the first year, whereas those on the neck become covered with hair.

Neonatal Urticaria (Erythema Toxicum)

Neonatal urticaria is a common rash that usually starts on the second or third day of life. There are white pinpoint papules at the center of an erythematous base. Eosinophils are present on microscopy. The lesions migrate to different sites (see Chapter 52).

Milia

Benign white cysts may be present on the nose and cheeks from retention of keratin and sebaceous material in the pilaceous follicles.

Epstein Pearls and Cysts of the Gums

Small white pearls may be visible along the midline of the palate (Epstein pearls).

Cysts of the gums (epulis) and on the floor of the mouth (ranula) are mucus-retention cysts and do not need any treatment.

Harlequin Color Change

In harlequin color change, there is longitudinal reddening down one half of the body and a sharply demarcated blanching down the other side. This lasts for a few minutes. It is thought to be due to vasomotor instability.

Breast Enlargement

Breast enlargement can occur in newborns of either sex. A small amount of milk ("witch's milk") may be discharged.

Hydroceles

The testis may feel enlarged on palpation; this is usually from a hydrocele, which can be confirmed on transillumination with a flashlight. Hydroceles are relatively common in boys and usually resolve spontaneously.

Vaginal Discharge

There may be a white vaginal discharge or small amount of bleeding from maternal hormone withdrawal. There may also be prolapse of a ring of vaginal mucosa.

Mongolian Blue Spots

Mongolian blue spots are blue-black macular discolorations at the base of the spine or on the buttocks. They occasionally also occur on the legs and other parts of the body. They occur most often in African-American or Asian infants and fade slowly over the first few years of life. They are of no clinical significance but are occasionally misdiagnosed as bruises.

Umbilical Hernia

Umbilical hernias are common, especially in African-American infants. No treatment is indicated because they usually resolve within the first few years of life.

SIGNIFICANT ABNORMALITIES DETECTED ON ROUTINE EXAMINATION

The prevalence of the most common significant congenital abnormalities is shown in Table 27-1. Some are detected prenatally, but many are first noted in the delivery room or during the routine examination of the newborn. These lesions are described briefly here but are considered in more detail elsewhere in the book.

Syndromes

Identification of abnormal facies and other abnormalities could lead one to suspect that the newborn has a syndrome. Down syndrome is by far the most common. The characteristic facies is often more difficult to recognize in the immediate neonatal period than in later life, but other abnormalities, such as the flat occiput, hypotonia, bilateral single palmar

TABLE 27–1 Prevalence of Serious Congenital Anomalies (per 1000 Live Births)

Anomaly	Prevalence
Congenital heart disease	6-8 (0.8 identified in the first day of life)
Developmental dysplasia of the hip	0.8 (about 7/1000 have an abnormal initial examination)
Talipes equinovarus	1.5
Down syndrome	1.3
Cleft lip and palate	0.8
Urogenital (hypospadias, undescended testes)	1.2
Spina bifida/anencephalopathy	0.5

creases, and a pronounced sandal gap (an abnormal skin crease between the first two toes), are helpful additional signs. In practice, the parents usually need to be informed of the diagnosis before the results of the chromosome analysis are available.

Many hundreds of syndromes have been described. When the diagnosis is uncertain, a book or computer database should be consulted and advice sought from a pediatrician or clinical geneticist (see Chapter 29).

Craniosynostosis

In craniosynostosis, there is premature fusion of one or more of the cranial sutures usually resulting in a markedly asymmetric skull with a palpable ridge along the suture line. It may be isolated, but if more than one suture is involved, it is often part of a syndrome (e.g., Crouzon or Apert syndrome). Because it may restrict brain growth, surgery may be required to avoid neurologic impairment and to improve the cosmetic outcome.

Port-Wine Stain (Nevus Flammeus)

Port-wine stains are caused by a vascular malformation of capillaries in the dermis. They are usually present at birth. When these lesions are disfiguring, their appearance can be improved using laser therapy. Port-wine stains affecting the distribution of the trigeminal nerve may be associated with intracranial vascular anomalies (Sturge-Weber syndrome). Severe lesions on the limbs are associated with bone hypertrophy (Klippel-Trénaunay syndrome). Port-wine stains must be differentiated from strawberry nevi (cavernous hemangiomas), which are not present at birth but appear during the first 1 or 2 months of life.

Brachial Plexus Lesions

Brachial plexus lesions cause lack of active movement of the affected limb; passive movement is not painful or restricted. The most common is Erb palsy from an upper root palsy (C5, C6, and sometimes C7). The arm is held internally rotated and pronated in the "waiter's tip" position. Although most brachial plexus injuries resolve, those that do not recover steadily during the first 2 months of life or that are severe should be seen by a specialist because surgical repair may be indicated. Accompanying respiratory symptoms may be secondary to damage of phrenic nerve roots (see Chapter 28).

Fracture of the Clavicle

Clavicle fractures most often occur during difficult delivery of the shoulders. A lump on the clavicle may be palpated or observed or identified because the infant keeps the arm immobile. It results from callus around a fracture and will heal without treatment. An asymmetric Moro reflex is another clue to identify a fractured clavicle.

Eye Abnormalities

On checking the eyes with an ophthalmoscope, the cornea may be opaque from a congenital cataract or enlarged and hazy from congenital glaucoma. A coloboma is a defect in the iris, resulting in a keyhole-shaped pupil. It may be associated with a defect in the retina. It may be an isolated abnormality or part of the CHARGE syndrome (coloboma, heart disease, atresia choanae, restriction of growth or development, genitourinary tract abnormality, ear anomalies). Newborns with these eye abnormalities should be referred immediately to an ophthalmologist.

Cleft Lip and Palate

If cleft lip and palate are recognized prenatally, the parents will be forewarned and counseled about the likely appearance and management. When diagnosed at birth, the parents will need to be reassured about the good cosmetic results after surgical repair. Before and after photographs of other children are often helpful. Assistance in establishing feeding may be required. The infant will need to be referred to a multidisciplinary craniofacial service.

Micrognathia

Micrognathia may be associated with glossoptosis and a posterior cleft palate (Pierre Robin sequence) and may cause upper airway obstruction.

Neck Abnormalities

Redundant skin over the posterior neck, together with a flat occiput, are features of Down syndrome. A webbed neck is a feature of Turner syndrome, which may also be associated with lymphedema of the feet. A short webbed neck may indicate abnormalities of the cervical spine (Klippel-Feil syndrome). Cystic hygromas are soft, fluctuant swellings that transilluminate.

Ear Abnormalities

Malformations of the ear may be associated with hearing loss. Affected infants should have their hearing checked. Skin tags anterior to the ear (preauricular tags) and accessory auricles should be removed by a plastic surgeon. Preauricular tags are usually isolated and benign. They are sometimes associated with other dysmorphic features, a family history of deafness, maternal history of gestational diabetes, and increased risk for renal anomalies. When a preauricular tag is associated with other abnormalities or risk factors, a renal ultrasound is recommended.[45] The need for a renal ultrasound examination for an isolated preauricular tag has been questioned because the incidence of renal tract anomalies in these circumstances has been reported to be similar to that in the general population.[13] Congenital ear deformities, in which there is normal development of the ear cartilage but abnormal architecture, may resolve spontaneously, but in some of these patients, surgery is performed. Splinting of the ears in the early neonatal period has been suggested to avoid the need for surgery and improve cosmetic appearance.[31]

Extra Digits

Extra digits are usually connected by a thin skin tag but can be completely attached and contain bone. Extra digits containing bone should be removed by a plastic surgeon; many pediatricians tie off thin skin tags with a silk thread, but care needs to be taken to avoid having a remaining stump of skin. Polydactyly may be familial, but it can also be caused by a dysmorphic syndrome.

Heart Murmurs

Heart murmurs can be heard in about 0.6% of infants at the routine examination of the newborn.[1] Most are innocent and originate from the acute angle at the pulmonary artery bifurcation or are from a patent ductus arteriosus or tricuspid regurgitation.[5] The problem is to differentiate innocent murmurs from those caused by significant heart lesions. Clinical features may serve as a guide. Features of innocent and significant murmurs are given in Box 27-3. These clinical criteria can help residents,[18] general pediatricians,[14,25] and pediatric cardiologists[41] to identify significant heart lesions.

The usefulness of electrocardiograms and chest radiographs in helping to distinguish innocent from significant murmurs is controversial. The neonatal electrocardiogram and chest radiograph are difficult to interpret, and these tests have rarely been found to change decisions based on the clinical examination.[41,43] Many centers have stopped performing them under these circumstances.

If a heart murmur is thought to be significant or cannot confidently be diagnosed as innocent, the infant should be referred directly for echocardiography. The management of infants with an innocent murmur depends on the availability of echocardiography. If echocardiography is readily available, it can be performed directly and provides parents with a definitive diagnosis without delay. If echocardiography is not readily available, a follow-up medical examination should be arranged soon after discharge and the parents warned to seek medical assistance if their infant becomes symptomatic with poor feeding, labored breathing, or cyanosis.

Most innocent murmurs disappear in the first year of life, most in the first 3 months. However, any mention of a heart murmur can create considerable parental anxiety, which sometimes continues for years. Attention must be paid to this to prevent parents from continuing to worry about their child's heart after the murmur has disappeared.[48]

BOX 27–3 Features of a Heart Murmur in a Neonate

FEATURES OF AN INNOCENT MURMUR
- Soft (grade 1/6 or 2/6) murmur at left sternal edge
- No audible clicks
- Normal pulses
- Otherwise normal clinical examination

FEATURES SUGGESTING A MURMUR IS SIGNIFICANT[33]
- Pansystolic
- Loud (≥grade 3/6)
- Harsh quality
- Best heard in the upper left sternal edge
- Abnormal second heart sound
- Femoral pulses difficult to feel
- Other abnormality on clinical examination

Midline Abnormality over the Spine or Skull

Spina bifida is often diagnosed prenatally. Affected infants must be referred to a neurosurgical service. A nevus, swelling, or tuft of hair along the spine or middle of the skull requires further evaluation because it might indicate an underlying abnormality of the vertebrae, spinal cord, or brain. Ultrasound or magnetic resonance imaging delineates the anatomy. Sacrococcygeal pits are common and harmless, whereas a dermal sinus above the natal clefts should be investigated because it might extend into the intraspinal space and place the infant at increased risk for meningitis.[20]

Single Umbilical Artery

Single umbilical artery occurs in about 0.3% of newborns. It is associated with an increased risk for chromosomal abnormalities and congenital malformations, particularly of the genitourinary system.[19,30] A single umbilical artery was associated with asymptomatic renal anomalies in 7% in one series.[8] The yield is low from ultrasound screening of the kidneys and urinary tract when this is an isolated finding,[44] and most renal abnormalities identified are transient or mild. The yield is further reduced by routine prenatal ultrasound screening for congenital anomalies of the kidneys and urinary tract. It is probably best reserved for those who also have other anomalies on physical examination.

Enlarged Kidneys or Bladder

If palpation of the abdomen detects abnormally large renal masses or an enlarged bladder in a male infant, ultrasonography is required urgently to identify urinary outflow obstruction. Most cases of urinary outflow obstruction are now detected on prenatal ultrasound screening, as are other major abnormalities of the kidneys and urinary tract. Siblings of children with vesicoureteric reflux should be screened for this condition because up to 40% are also affected.[40]

Abnormalities of the Genitalia

A penis less than 1 cm long is a micropenis suggesting hypopituitarism. In hypospadias, the urethral meatus is in an abnormal position, usually on or adjacent to the glans penis, but may be on the penile shaft or perineum. The foreskin is hooded, and chordee, causing ventral curvature of the shaft of the penis, may be present. Glanular hypospadias without chordee may not require treatment, but more severe forms require corrective surgery, and a specialist's opinion should be sought and circumcision withheld.

An undescended testis has failed to descend from its embryologic position from the urogenital ridge on the posteriorly abdominal wall through the inguinal canal to the scrotum. At birth, about 4% of full-term male infants have an undescended testis; by 3 months, about 1% are still undescended, with little reduction thereafter. An undescended testis should be rechecked at several months of age. If still undescended, referral to a pediatric surgeon or urologist is indicated. If both testes are undescended, is this a virilized female with congenital adrenal hyperplasia?

Neonatal testicular torsion usually occurs before birth. A pediatric surgeon should be consulted urgently, although the testis is rarely salvageable because it has usually already undergone infarction.

Talipes

In positional talipes, the feet are turned inward from intrauterine compression, especially if there was oligohydramnios. The foot is of normal size and can be fully abducted and dorsiflexed to the neutral position, and the dorsal surface of the foot can be brought into contact with the anterior lower leg by passive manipulation. If this maneuver can be performed, no treatment is required; the parents can be shown passive exercises. With talipes equinovarus, the affected foot is shorter than normal. The entire foot is inverted and supinated, and the forefoot is adducted. The heel is rotated inward and in plantar flexion. The position of the foot is fixed and cannot be corrected completely. It may be secondary to oligohydramnios during pregnancy, a feature of a malformation syndrome, or a feature of a neuromuscular disorders such as spina bifida. The infant must be referred directly to a pediatric orthopedic surgeon. Feet in the calcaneus valgus position are usually maintaining the position of the feet in utero. It should be possible to dorsiflex the foot to bring its dorsal surface into contact with the anterior lower leg and to achieve normal plantar flexion. If this can be achieved, spontaneous resolution can be expected.

LIMITATIONS OF THE ROUTINE EXAMINATION

Examination of a newborn in the delivery room and at a routine examination will identify a number of problems, many of which are transient, although some are permanent and significant. However, some significant abnormalities will not be identified. Sometimes this is due to inexperience of the examiner or the difficulty of performing a satisfactory examination in an uncooperative newborn (e.g., getting a good view of the eyes and red reflex, hearing a heart murmur, or testing for DDH). However, some significant abnormalities will not be identified because of the limitations of the examination.

Parents might become upset or angry when it becomes evident at a later stage that their child has a significant problem. They need to be made aware that not all abnormalities can be detected at the initial examination. This situation also stresses the importance of clear documentation of the routine examination for future reference. Some of the major limitations of the clinical examination are listed next.

Identification of Syndromes

Some syndromes can be difficult or impossible to identify in the immediate neonatal period but become apparent as the child grows older.

Jaundice

Jaundice usually develops after 24 hours of age, unless it is due to hemolysis. Significant jaundice can develop at several days of age even though the infant was apparently normal only 1 or 2 days earlier (see Chapter 48).

Eye Abnormalities

Vision is better if surgery for congenital cataracts is performed before 8 weeks of age. However, a survey in the United Kingdom revealed that only 35% of congenital cataracts were identified on the routine examination.[37] This demonstrates the difficulty in early recognition of eye abnormalities during the routine examination of the newborn. Deficiency in training of health care professionals[38] and the rarity of serious eye conditions, occurring in only 0.5 per 1000 live births, contributes to the low rate of diagnosis.

Congenital Heart Disease

Six to 8 infants per 1000 live births have congenital heart disease. In a retrospective review of infants with congenital heart disease born between 1987 and 1994, 33% presented before the routine examination with symptoms or noncardiac abnormalities, 30% had an abnormal routine examination, and 37% had a normal routine examination.[47] At discharge from the hospital, a cardiac diagnosis or referral was made in 43% of infants with congenital heart disease, but one third of the remaining infants presented with symptoms or died from their cardiac condition by 6 weeks of age. This review highlights the limitations of the routine examination in identifying significant structural heart disease.

The first is that the newborn examination may be normal even when the infant has a significant or even lethal structural heart lesion. At the time of the newborn examination, the pressure in the right side of the heart is still relatively high, and the ductus arteriosus may still be patent. Infants with a ventricular septal defect (the most common congenital heart lesion) or other heart lesions might not have a heart murmur at the routine examination because the pressure difference between the left and right sides of the heart will be insufficient to generate turbulent flow at this stage.

A second reason is that infants with ductus-dependent lesions can present clinically with heart failure, shock, cyanosis, or death just days or weeks after a normal routine examination. Femoral pulses may be palpable at the initial examination because of blood flow through the ductus arteriosus.

An additional limitation is that a heart murmur may be heard but because most are innocent, those from significant heart lesions are not always identified. Prenatal diagnosis of some severe heart lesions and the increasing availability of echocardiography should reduce, but will not eliminate, failure to identify structural heart lesions before discharge from the hospital.

Pulse oximetry screening has been advocated to assist the detection of ductal dependent lesions. This has included population-based prospective studies using postductal (foot) arterial oxygen saturation ($\mathrm{SpO_2}$) of less than 95% [32] or $\mathrm{SpO_2}$ measured preductally (right hand) and postductally (foot) and considered abnormal if both $\mathrm{SpO_2}$ measurements were less than 95% or the difference between the two measurements was greater than or equal to 3%.[23] These and other studies have shown that pulse oximetry screening before discharge improves the detection rate of ductal-dependent circulation, but has not been aopted for universal screening.

Developmental Dysplasia of the Hip

As a screening test, clinical examination for DDH presents problems.[11] Ideally, all affected infants should be identified in the neonatal period because early treatment prevents or reduces the need for surgery. In practice, a significant fraction of infants who subsequently require surgery are not identified in the neonatal period. A survey from the United Kingdom suggested that the operative rate, 0.7 per 1000 live births, has remained unchanged since screening was introduced.[22] Another study from South Australia found a lower operative rate, at 0.45 per 1000 births, but still only 56% of these infants were identified at the initial clinical examination.[10] However, DDH was diagnosed in 7.7 per 1000 live births, indicating that the hips of most infants with an abnormal neonatal hip examination are normal.

An examiner might fail to identify DDH at the initial examination because the examiner is inexperienced or because the examination is suboptimal when the infant is not relaxed. In some infants with a flat acetabular shelf, the clinical examination may be normal in the neonatal period, but the dysplasia progresses with age.[39] Also, the irreducible dislocated hip is easily missed on examination.

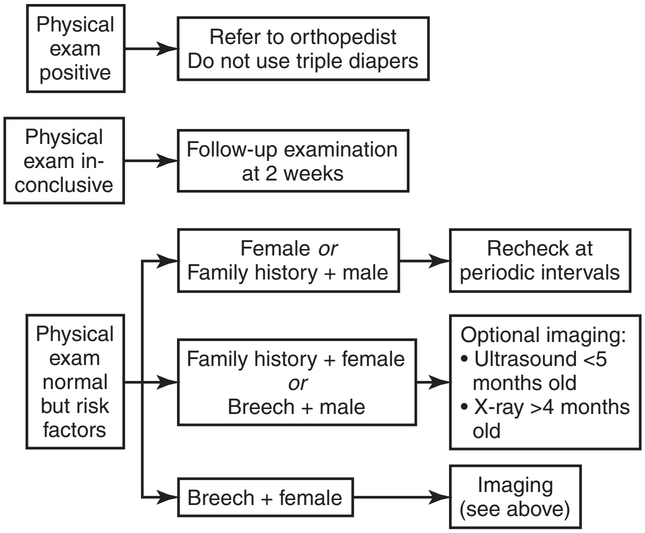
The risk for DDH is increased in female infants, in those with a positive family history, and in infants with a breech presentation. The absolute risk for a positive result on routine examination of the newborn is shown in Table 27-2. The risk is also increased in infants with a neuromuscular disorder.

Two strategies can improve the detection rate of DDH in newborn infants. The hip examination can be performed by pediatric orthopedists, or imaging of the hips can be performed. Ultrasound will identify DDH, including a shallow acetabular shelf. However, ultrasound has a high false-positive rate, and it is only helpful in the first 5 months of life. Alternatively, a hip radiograph will identify DDH but only after 4 months of age. The imaging can be performed on all infants or only on high-risk infants or on those with a positive examination.

TABLE 27–2 Absolute Risk for a Positive Result on Routine Examination of the Newborn Hip

Newborn Characteristics	Absolute Risk for a Positive Examination per 1000 Newborns
Overall	
All newborns	11.5
Boys	4.1
Girls	19
Positive Family History	
Boys	6.4
Girls	32
Breech Presentation	
Boys	29
Girls	133

From American Academy of Pediatrics: Clinical practice guideline: early detection of developmental dysplasia of the hip, *Pediatrics* 105:896, 2000.



Physical exam positive
Refer to orthopedist
Do not use triple diapers
Physical exam in-conclusive
Follow-up examination at 2 weeks
Physical exam normal but risk factors
Female *or* Family history + male
Recheck at periodic intervals
Family history + female *or* Breech + male
Optional imaging:
• Ultrasound <5 months old
• X-ray >4 months old
Breech + female
Imaging (see above)

Figure 27–2. Management of newborn infants with physical examination that is positive for developmental dysplasia of hip, inconclusive, or normal with risk factors. *(From American Academy of Pediatrics: Clinical practice guideline: early detection of developmental dysplasia of the hip,* Pediatrics *105:896, 2000. Copyright © 2000 by the AAP.)*

All these options have been considered in detail in the American Academy of Pediatrics guidelines on early detection of DDH.[3] They recommend that the clinical procedure be performed by a properly trained health care provider. Management options for infants with a positive or inconclusive test and for those with a risk factor are summarized in Figure 27-2.

HEALTH PROMOTION

The routine examination is an opportunity to promote preventive health care.

Prevention of Sudden Infant Death Syndrome

All parents should be advised that infants should sleep on their backs and that overheating and parental smoking are risk factors. Also, bed-sharing and co-sleeping should be avoided. Attention to preventive measures has markedly reduced the incidence of sudden infant death syndrome in many countries.

Promotion of Breast Feeding

Mothers should be encouraged in and assisted with breast feeding.

Hearing and Vision Screening

Children with increased risk for deafness (e.g., family history, malformations of the ear including skin tags and pits)[28] must be referred for early hearing testing. Universal hearing screening should be performed per hospital protocol. Similarly, infants at increased risk for vision loss should be referred to an ophthalmologist. The parents should be given advice about early detection of hearing and vision loss.

Immunization

The routine examination is an opportunity to reinforce the importance of immunization.

Safe Transport

The newborn period is a good opportunity to provide advice on the need for car seats for infants.

REPEAT EXAMINATION

With shortened stay of healthy newborns in the hospital, performing a second full routine examination at discharge is of limited value in identifying additional abnormalities.[21,34] More important, the routine examination must be performed by a properly trained health care professional. For example, advanced neonatal nurse practitioners were found to be more effective than trainee pediatricians in detecting abnormalities.[29]

Criteria that must be met for the early (<48 hours) discharge of term infants have been published.[12] Before any infant is discharged, the health care provider should check that the infant has fed satisfactorily on at least two successive occasions, is not jaundiced or the bilirubin has been measured and a follow-up plan is in place, is breathing normally, and has urinated and passed stool. The clinician must also ensure that the mother is able to care adequately for her infant and that the infant is going to a suitable environment. The initial hepatitis B immunization should have been given, and hepatitis B Immunoglobulin if indicated by the infant's risk status. Follow-up care for the infant should also be in place.

ASSESSMENT OF GESTATIONAL AGE

Formal assessment of gestational age is unnecessary for the routine newborn examination. The best guide to an infant's gestational age is an early antenatal ultrasound evaluation combined with information about the mother's last menstrual period. An evaluation of the clinical methods of assessing gestational age showed that clinical methods had 95% confidence intervals of 17 days, whereas the antenatal ultrasound had 95% confidence intervals of less than 7 days.[46] Clinical assessment is most important for infants whose gestational age is unknown or discrepant with their growth.

Four methods can be employed to assess gestational age: physical criteria,[17,35] neurologic examination,[4] combined physical and neurologic examination,[6,15] and examination of the lens of the eye.[26] Physical criteria are used to establish gestational age because they progress in an orderly fashion with increasing gestation. The assessment of gestational age using neurologic criteria involves the assessment of posture, passive and active tone, reflexes, and righting reaction.[4]

Gestational age can be assessed most accurately by combining the physical criteria and the neurologic assessment. Dubowitz and Dubowitz described and developed such a combined scoring system.[16] Its disadvantage is that it involves assessing 11 physical criteria and 10 neurologic findings. Although the physical criteria allow clear distinction of infants with gestational ages older than 34 weeks, neurologic criteria are essential to differentiate infants between 26 and 34 weeks because the physical changes are less evident. Ballard and colleagues abbreviated the Dubowitz scoring system to include 6 neurologic and 6 physical criteria to shorten the time taken. The revised Ballard examination (Fig. 27-3) includes assessment for extremely premature infants.[7] Regardless of the method used, the assessment of gestational age using physical and neurologic criteria is accurate only to ±2 weeks, with a tendency toward overestimation in extremely premature infants.

NEUROLOGIC ASSESSMENT

A detailed neurologic assessment is performed in infants with a neurologic problem. The infant's neurologic evaluation combines elements of the standard neurologic examination and a developmental assessment of gestational age (Box 27-4). It also highlights the marked effect of gestational age on neurologic development. With experience, the examiner can accomplish the evaluation with minimal or no discomfort to the infant, an important goal, especially in fragile premature infants. The neurologic examination includes the components described next.

Level of Consciousness

Newborn infants' states of alertness at term are usually categorized[36] as follows:

State 1 (deep or quiet sleep): eyes closed, regular respiration, no movements
State 2 (light or rapid eye movement sleep): eyes closed, irregular respiration, no gross movements
State 3 (awake, drowsy): eyes open, no gross movements
State 4 (alert): eyes open, gross movements, no crying
State 5 (crying): eyes open or closed, crying

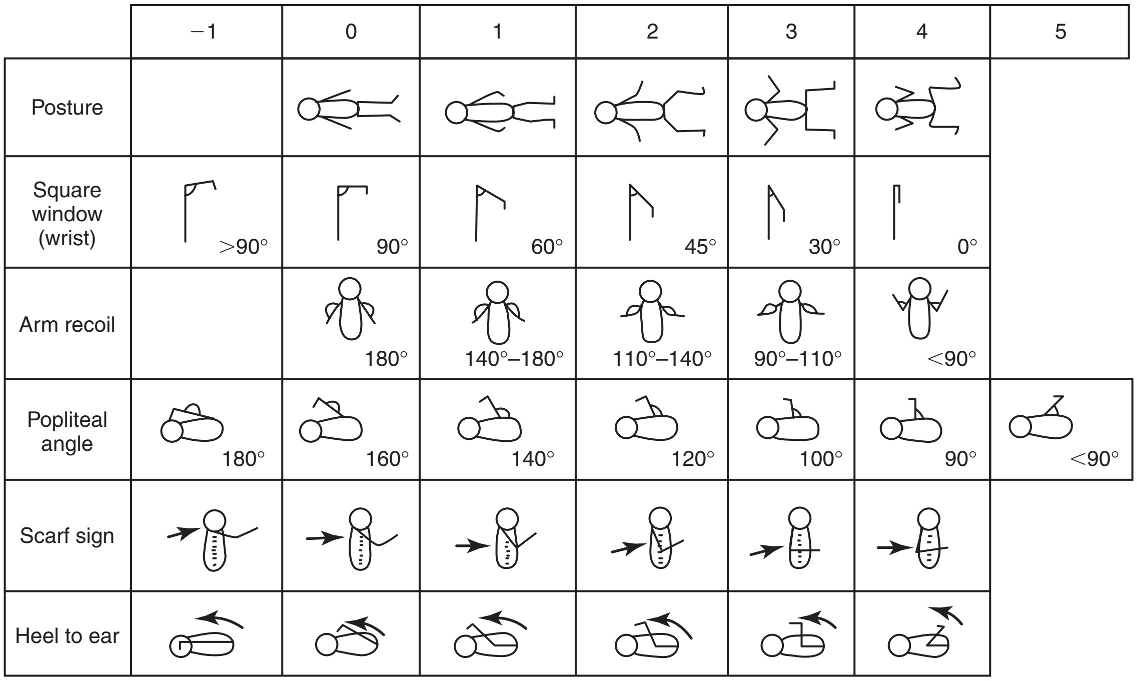
For optimal neurologic examination, a term infant should be alert and not crying (state 3). An infant who is persistently in states 1 and 2 is likely to be abnormally lethargic; if persistently in state 5, abnormally hyperexcitable. The cry may also be abnormal (e.g., high pitched from cerebral irritation, incessant from drug withdrawal).

Inspection

The physical component of the neurologic examination includes visual inspection and palpation of the head, spine, and extremities. The entire body is observed for visibly apparent congenital anomalies, birthmarks, or bruises. The head and spine are palpated to ascertain the presence of deformities, the position of the sutures, and the size and shape of the fontanelles.

The size and shape of the head provide important information regarding the occurrence of an insult to the fetal brain. When fetal brain growth has been compromised, head size is decreased relative to body length, and sutures might overlap. In contrast, a large head with widely separated sutures

NEUROMUSCULAR MATURITY



PHYSICAL MATURITY

Skin	Sticky, friable, transparent	Gelatinous red, translucent	Smooth pink, visible veins	Superficial peeling and/or rash, few veins	Cracking pale areas, rare veins	Parchment, deep cracking, no vessels	Leathery, cracked, wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	
Plantar surface	Heel–toe 40–50 mm: −1 <40 mm: −2	>50 mm no crease	Faint red marks	Anterior transverse crease only	Creases ant. 2/3	Creases over entire sole	
Breast	Imperceptible	Barely perceptible	Flat areola, no bud	Stippled areola 1–2 mm bud	Raised areola 3–4 mm bud	Full areola 5–10 mm bud	
Eye/ear	Lids fused loosely: −1 tightly: −2	Lids open; pinna flat, stays folded	Sl. curved pinna; soft; slow recoil	Well-curved pinna; soft but ready recoil	Formed and firm instant recoil	Thick cartilage, ear stiff	
Genitals, male	Scrotum flat, smooth	Scrotum empty; faint rugae	Testes in upper canal; rare rugae	Testes descending; few rugae	Testes down; good rugae	Testes pendulous; deep rugae	
Genitals, female	Clitoris prominent, labia flat	Prominent clitoris, small labia minora	Prominent clitoris, enlarging minora	Majora and minora equally prominent	Majora large, minora small	Majora cover clitoris and minora

BOX 27–4 Neurologic Evaluation

General appearance
Level of consciousness
Mechanical signs: head spine, extremities
Cranial nerves
Motor: strength, tone, movements
Deep tendon reflexes
Primitive reflexes: Moro, grasp, suck, root
Autonomic: heart rate pattern, respiratory pattern, bladder function, bowel function

denotes an underlying large brain, usually the consequence of congenital obstructive hydrocephalus. Postnatally, a rapidly expanding head with widely separated sutures indicates cerebral edema, epidural or subdural hemorrhage, or acquired, progressive hydrocephalus, which may result from intraventricular hemorrhage in a premature infant.

Cranial Nerves

Despite the inability of the examiner to communicate/verbally with the infant, the functions of most of the 12 cranial nerves can be determined in the newborn infant (Table 27-3). Indeed, cranial nerve evaluations can be conducted even in premature infants near the lower limit of viability.

Cranial nerve I (olfactory) is typically not examined, given its rare involvement by a disease process and the infant's difficulty to provide an appropriate response.

Vision (cranial nerve II [optic]) is assessed both subjectively and objectively. Healthy full-term and older premature infants fixate on and track the examiner's face or a card with concentric black and white circles presented 20 to 30 cm from the infant's face. Horizontal eye movements are more easily elicited than are vertical eye movements. Visual orientation and tracking are considered cerebral cortical functions.

The pupillary light reflex also assesses optic nerve integrity but is a subcortical function and requires an intact efferent limb, specifically the autonomic component of cranial nerve III (oculomotor). Those nerves that subserve extraocular movements include cranial nerves III, IV, and VI (oculomotor, trochlear, and abducens, respectively).

Eye movements in all directions of gaze occur spontaneously or can be induced with oculocephalic maneuvers (doll's eye reflex). The doll's eye reflex is typically elicited with the infant in the supine position by simply turning the head from one side to the other, whereon the eyes will deviate in the opposite direction. Vertical eye movements can be ascertained by flexing or extending the head. Alternatively, the infant can be removed from the crib, suspended in the vertical plane, and rotated clockwise or counterclockwise. The eyes will deviate in the direction opposite the spin. Rotation in the axial plane induces vertical eye movements.

The eyes are observed for the presence or absence of ptosis. Unilateral or bilateral ptosis occurs as a consequence of dysfunction either of cranial nerve III, which innervates the palpebral muscle (upper eyelid only), or of ascending sympathetic nerves, which course through the neck to innervate the tarsal plates (both eyelids). Oculomotor nerve dysfunction producing ptosis is often associated with ipsilateral pupil dilation, whereas sympathetic nerve dysfunction producing ptosis is associated with ipsilateral pupil constriction (Horner syndrome).

Cranial nerve V (trigeminal) has both sensory and motor functions. Corneal and facial sensations can be tested if

TABLE 27–3 Cranial Nerve Examination

Nerve	Name	Function	Evaluation Method
I	Olfactory (and track)	Smell	Not tested
II	Optic (and retina)	Visual acuity and fields	Facies or object with black and white concentric circles
III	Oculomotor response, lid elevation	Extraocular movements; pupillary reflex	Observation of tracking; doll's eye reflex
IV	Trochlear	Extraocular movements	Observation of tracking; doll's eye reflex
V	Trigeminal	Mastication; facial sensation	Corneal and suck reflexes; nasal stimulation
VI	Abducens	Extraocular movements	Observation of tracking; doll's eye reflex
VII	Facial	Facial expression; taste	Nasal stimulation; corneal and sucking reflexes
VIII	Auditory	Hearing; spatial orientation	Sounds and behavioral response; doll's eye reflex
IX	Glossopharyngeal	Swallowing; vocalization	Sucking and swallowing reflex; gag reflex; quality of cry
X	Vagus	Swallowing; vocalization	Sucking and swallowing reflex; gag reflex; quality of cry
XI	Spinal accessory	Head and shoulder movement	Observation
XII	Hypoglossal	Tongue movement	Observation; atrophy; fasciculations

indicated with a wisp of cotton applied to each cornea to elicit a rapid blink or to the nares to elicit a facial grimace. The motor component of cranial nerve V subserves jaw (mandibular) opening and closure, which are best tested by observing the infant's sucking ability. A persistently open mandible suggests trigeminal motor paralysis.

Cranial nerve VII (facial) controls all superficial facial movements, including eyelid closure, and taste, which is rarely tested. Facial movements occur spontaneously and are a component of the sucking and rooting reflexes. Tickling the nares with a wisp of cotton should induce facial grimacing, whereon either unilateral or bilateral facial paresis will become apparent.

Cranial nerve VIII subserves both hearing (auditory) and vestibular functions (see Chapter 42). Hearing is tested either subjectively or objectively, the latter by eliciting the brainstem auditory evoked response. Subjective testing at crib side is typically accomplished with the use of a bell presented to either ear, observing for increased alertness and possibly an orienting response. Initially, the sound of the bell should be of low intensity, increasing in loudness until a response is obtained. The vestibular component of cranial nerve VIII is not specifically tested other than through its interaction with brainstem pathways, which subserve reflex eye movements.

The functions of cranial nerves IX and X (glossopharyngeal and vagus, respectively) are combined to control swallowing function and vocalization. Voluntary motor functions are tested by observing the infant's sucking and swallowing abilities. In addition, the position and movement of the soft palate are observed with the aid of a tongue depressor and flashlight. The gag reflex is then tested with a tongue depressor. During the oral evaluation, cranial nerve XII (hypoglossal) function is tested by examining the tongue, noting its position, movement, and bulk. The presence of tongue fasciculations is noted, which consist of random, wormlike movements best appreciated along the lateral tongue margins and which may be observed in spinal muscular atrophy. Atrophy of the tongue is observed as scalloping of its margins. Tongue fasciculations must be distinguished from tremors, the latter consisting of normal rhythmic movements of the structure accentuated by its protrusion during crying.

Cranial nerve XI (spinal accessory) is a pure motor nerve. It innervates the sternocleidomastoid muscle of the neck to produce either lateral or anterior flexion of the head, depending on contraction of one or both muscles. The nerve also innervates the trapezius muscle of the shoulder to produce shoulder elevation. These functions typically are tested by simple observation of head and shoulder movements.

Motor Function

The motor system examination includes tests of skeletal muscle posture, tone, and movement. During the initial period of general observation, the position of the extremities is noted for flexion, extension, or neutral postures. Healthy, full-term infants typically exhibit flexion of the arms at the elbows and of the legs at the knees (Fig. 27-4). Fisting of the hands, including adduction and in-folding of the thumbs (cortical thumbs), is usual with intermittent hand opening.

Limb position and posturing are relatively symmetric, although the infant manifests spontaneous movements that are often asymmetric and jerky. Limb posture (flexion or extension) also is influenced by the position of the head. If the head is turned to one side, there is often extension of the ipsilateral arm and leg and flexion of the contralateral extremities (asymmetric tonic neck reflex). While prone, the full-term infant maintains a flexed posture of the arms and legs, with resultant elevation of the pelvis as well as hip and knee flexion.[42]

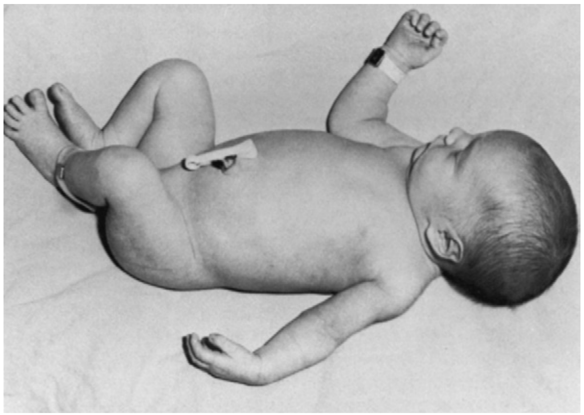

Figure 27–4. Full-term newborn at rest. Note that the posture of the arms and legs is slightly asymmetric. The arms are partially flexed, whereas the legs are flexed at the hips and knees.

Tone is characteristic of skeletal muscle because of an intrinsic resistance to stretch that can be either active or passive. Muscle at rest resides in a state of partial relaxation, and energy is required for its full contraction. Elongation requires further muscle relaxation and concurrent contraction of the opposing or antagonistic muscle. Thus, normal muscle tone depends on a sophisticated interaction between agonistic and antagonistic muscles, which are influenced by innervating peripheral nerves (sensory and motor) as well as by the central nervous system. Given the strategic role played by skeletal muscle in neurologic function, it is not surprising that alterations in muscle tone represent the clinical hallmark of a variety of neurologic disease processes.

The assessment of muscle tone includes observation of the infant's posture and movement as well as the production of an active or passive range of motion. If feasible, the infant should be suspended in the horizontal plane and the attitude and posture of the head, trunk, and extremities observed. Thereafter, the infant is held in the vertical plane to ascertain the extent and symmetry of flexor tone of the extremities. While the infant lies supine, the upper and lower extremities are extended and flexed to ascertain the presence and extent of resistance. Head control can be determined by lifting the supine infant from the surface by either the shoulders or hands.

Increased resistance to passive movement indicates hypertonicity (rigidity, spasticity), whereas reduced resistance and unrestricted movement indicate hypotonicity. In this regard, the neurologic component of the Dubowitz and Ballard scoring systems for determining gestational age largely reflects the maturation of muscle tone in premature infants. Infants who are hypertonic often exhibit an opisthotonic posture in conjunction with obligate extension when suspended in either the vertical or horizontal plane. Scissoring of the legs might be evident. In contrast, the hypotonic infant, when held in the vertical plane, tends to slide through the examiner's hands. In the horizontal plane, the infant drapes over the examiner's arms.[42]

Hypotonia should not be equated with weakness, which is a reduction in muscle strength or power, whether it is partial (paresis) or complete (paraplegia) paralysis. Muscle weakness is ascertained through observation of spontaneous or sensation-induced movements of the extremities. Although muscle hypotonia and weakness often occur together, hypotonia can be seen in the absence of weakness (e.g., cerebellar dysfunction), and weakness can occur when muscle tone is normal or even increased (e.g., spastic paralysis). Indeed, hypotonia combined with weakness typically denotes an intrinsic disease of the peripheral nervous system (nerve or muscle), whereas hypotonia with a preservation of muscle strength denotes a disturbance of the brain or spinal cord.

Deep Tendon Reflexes

Deep tendon reflexes are elicited as they are for older children and adults. The limb should be positioned in partial flexion and the appropriate tendon tapped with an infant reflex hammer. The head should be maintained in the neutral position to prevent inducing an asymmetric tonic neck response, which produces asymmetric reflex activity. Typically, upper extremity deep tendon reflexes are more difficult to elicit than lower extremity reflexes. In newborn infants, the Achilles tendon is not tapped directly; the reflex is elicited by tapping a thumb positioned on the plantar surface of the partially dorsiflexed foot.

Interpretation of the results of testing deep tendon reflexes is more problematic in neonates than older children but may help to confirm an asymmetric lesion. Ankle clonus is common and usually normal in the neonatal period. Eliciting plantar responses is not worthwhile because their interpretation presents problems.[27,42] At this age, the plantar response is usually said to be extensor, but it mainly depends on the strength of the stimulus applied; a gentle stimulus will often induce a flexor response.

Developmental Reflexes

The most frequently elicited primitive or developmental reflexes include the rooting, sucking, grasp, and Moro responses. These reflexes are fully developed and strong in the healthy, full-term newborn and typically disappear in the months to follow. Their persistence beyond the anticipated age of disappearance is an indicator of underlying central nervous system dysfunction. Other, less commonly induced primitive reflexes include the crossed extension, placing, and stepping reactions, all of which make their appearance by 36 to 38 weeks' gestational age.

Cerebral Cortical Function

Although newborn infants previously were believed to function predominantly or exclusively at a brainstem level, it has become increasingly apparent that neonates exhibit functions that involve activity of the cerebral cortex.[9] These functions include visual fixation and tracking as well as auditory alerting and localization. In addition, the phenomenon of habituation is considered a cerebral cortical function. Full-term newborns exhibit both visual and auditory habituation, which are elicited with a bright light and loud bell, respectively. The eyes are sequentially exposed to a bright light at a frequency of about 1 per second; the normal response is an initial strong blink followed by extinction after 3 to 5 exposures. A similar blink response occurs with repetitive auditory stimulations. Failure to respond initially to the sensory stimulation or a lack of habituation is an abnormal finding in an otherwise alert full-term newborn.

The Premature Infant

The neurologic signs in premature infants differ markedly with gestational age. In normal premature newborn infants, pupil responses to light are present, although sluggish, between 28 and 32 weeks' gestation and seldom present before 28 weeks (see Table 27-4). Oculocephalic (doll's eye) reflexes are complete and even exaggerated in infants as immature as 24 to 25 weeks. Paradoxically, the oculovestibular (caloric) reflex is incomplete before 28 to 30 weeks, with reduced medial displacement of the eye contralateral to the ear canal stimulated with cold water (intranuclear ophthalmoplegia). Corneal and gag reflexes are present in even the small premature infant, as is facial grimacing to nasal stimulation.

The newborn's responsiveness to the environment depends not only on the state of health but also on the gestational age. Infants of 25 to 30 weeks' gestation typically require intermittent arousal with external stimulation, and their waking periods are relatively short when compared with full-term infants. By 31 to 32 weeks' gestation, the premature infant exhibits reasonable alertness during wakeful stages. By term, the infant remains alert for prolonged periods during wakefulness and readily responds to visual, auditory, and tactile stimulation.

A notable difference in the neurologic status of the premature and full-term neonate is that of muscle tone. As indicated by the Dubowitz and Ballard scoring systems for gestational age, the more premature the infant at birth, the greater the muscle hypotonicity (see Fig. 27-3). The hypotonicity is especially apparent when measuring the popliteal and heel-to-ear angles and when executing the scarf sign. The maturational changes in muscle tone must be taken into account when evaluating newborns of varying gestational ages.

At and before 28 weeks' gestational age, a premature newborn is extremely hypotonic. When held in vertical suspension, the infant does not extend the head, trunk, or extremities. The maturational change from hypotonia of the small premature infant to the predominantly flexion posture of the full-term infant is manifest first in the legs and later in the arms and head. By 34 gestational weeks, the infant lies in a froglike position while supine; the legs are flexed at the hips and knees, but the arms remain extended and relatively hypotonic.

Developmental reflexes appear at specific ages of gestation to become fully developed and strong in the healthy full-term

TABLE 27–4 Neurologic Maturation of the Fetus and Newborn

Function	26 Weeks	30 Weeks	34 Weeks	38 Weeks
Resting posture	Flexion of arms Flexion or extension of legs	Flexion of arms Flexion or extension of legs	Flexion of all limbs	Flexion of all limbs
Arousal	Unable to maintain	Maintain briefly	Remain awake	Remain awake
Rooting	Absent	Long latency	Present	Present
Sucking	Absent	Long latency	Weak	Vigorous
Pupillary reflex	Absent	Variable	Present	Present
Traction	No response	No response	Head lag	Mild head lag
Moro	No response	Extension; no adduction	Adduction variable	Complete
Withdrawal	Absent	Withdrawal only	Crossed extension	Crossed extension

infant (Table 27-4). The sucking and rooting reflexes do not develop until 33 to 36 weeks' gestational age. The palmar and plantar grasp responses become apparent at about 28 weeks and are strong by 36 weeks. The Moro reflex makes its appearance at 24 to 26 weeks and evolves through 38 weeks, at which age the entire abduction-adduction response is present.

CHAPTER 28

Birth Injuries

Henry H. Mangurten and Bhagya L. Puppala

Birth injuries are those sustained during the birth process, which includes labor and delivery. They may be avoidable, or they may be unavoidable and occur despite skilled and competent obstetric care, as in an especially hard or prolonged labor or with an abnormal presentation. Fetal injuries related to amniocentesis and intrauterine transfusions and neonatal injuries after resuscitation procedures are not considered birth injuries. However, injuries related to the use of intrapartum monitoring of the fetal heart rate and collection of fetal scalp blood for acid-base assessment are included. Factors predisposing the infant to birth injury include macrosomia, prematurity, cephalopelvic disproportion, dystocia, prolonged labor, abnormal presentation, and certain operative deliveries, particularly vacuum extraction. The fetus may also sustain injury if the mother is involved in a motor vehicle collision, as reported by Parida and associates.[62] Although usually protected by maternal soft tissues, uterus, and amniotic fluid, the fetus may be subjected to the same acceleration-deceleration forces as the mother. This may result in full-thickness bowel injury and fulminant disseminated intravascular coagulation.[62] Thus, a thorough physical examination of the infant is critical after a maternal motor vehicle collision to identify any internal injury that may have occurred.

The significance of birth injuries may be assessed by review of mortality data. In 1981, birth injuries ranked sixth among major causes of neonatal death, resulting in 23.8 deaths per 100,000 live births.[90] During the ensuing decade, because of refinements in obstetric techniques and the increased use of cesarean deliveries over difficult vaginal deliveries, a dramatic decline occurred in birth injuries as a cause of neonatal death. Statistics for 1993 revealed a reduction to 3.7 deaths per 100,000 live births; because of the emergence of other conditions, birth injuries ranked 11th among major causes of neonatal death.[91] The most recent figures available (for 2006) identify only the five leading causes of infant death, with no mention of birth injuries.[55]

Despite a reduction in related mortality rates, birth injuries still represent an important source of neonatal morbidity and neonatal intensive care unit admissions. Of particular concern are severe intracranial injuries after operative vaginal delivery (vacuum-assisted and forceps delivery) and failed attempts at operative vaginal delivery.[24]

The clinician should consider the broad spectrum of birth injuries in the differential diagnosis of neonatal clinical disorders. Although many injuries are mild and self-limited, others are serious and potentially lethal. This chapter describes conditions that can be managed by observation only as well as those that require more aggressive intervention. In addition to assuring timely institution of therapy when indicated, recognition and documentation before discharge from the hospital will help avoid inappropriate suspicion of inflicted injury (child abuse) at a later date.

INJURIES TO SOFT TISSUES

Erythema and Abrasions

Erythema and abrasions frequently occur when dystocia has occurred during labor as a result of cephalopelvic disproportion or when forceps have been used during delivery. Injuries caused by dystocia occur over the presenting part; forceps injury occurs at the site of application of the instrument. Forceps injury frequently has a linear configuration across both sides of the face, outlining the position of the forceps. The affected areas should be kept clean to minimize the risk for secondary infection. These lesions usually resolve spontaneously within several days with no specific therapy.

Petechiae

Occasionally, petechiae are present on the head, neck, upper portion of the chest, and lower portion of the back at birth after a difficult delivery; they are observed more frequently after breech and precipitous deliveries and tight nuchal cord.

ETIOLOGY

Petechiae are probably caused by a sudden increase in intrathoracic and venous pressures during passage of the chest through the birth canal. An infant born with the cord tightly wound around the neck may have petechiae only above the neck.

DIFFERENTIAL DIAGNOSIS

Petechiae may be a manifestation of an underlying hemorrhagic disorder. The birth history, early appearance of the petechiae, and absence of bleeding from other sites help to differentiate petechiae caused by increased tissue pressure or trauma from petechiae caused by hemorrhagic disorders (see Chapter 46). The localized distribution of the petechiae, the absence of subsequent crops of new lesions, and a normal platelet count exclude neonatal thrombocytopenia. The platelet count also may be low because of infections or disseminated intravascular coagulation. Infections may be clinically distinguished from traumatic petechiae by the presence of other signs and symptoms. Disseminated intravascular coagulation usually is associated with excessive and persistent bleeding from a variety of sites. Petechiae usually are distributed over the entire body when associated with systemic disease.

TREATMENT

If the petechiae are caused by trauma, neither corticosteroids nor heparin should be used. No specific treatment is necessary.

PROGNOSIS

Traumatic petechiae usually fade within 2 or 3 days.

Ecchymoses

Ecchymoses may occur after traumatic or breech deliveries. The incidence is increased in premature infants, especially after a rapid labor and poorly controlled delivery. When extensive, ecchymoses may reflect blood loss severe enough to cause anemia and, rarely, shock. The reabsorption of blood from an ecchymotic area may result in significant hyperbilirubinemia (Fig. 28-1).

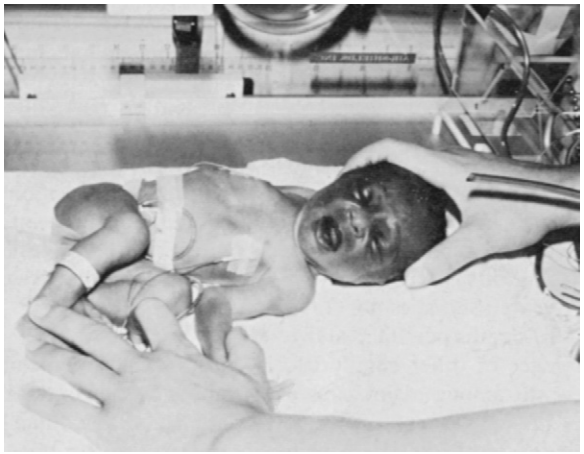

Figure 28–1. Marked bruising of entire face of a 1490-g female infant born vaginally after face presentation. Less severe ecchymoses were present on extremities. Despite use of phototherapy from the first day, icterus was noted on the third day, and exchange transfusions were required on the fifth and sixth days.

TREATMENT

No local therapy is necessary. The rise in serum bilirubin that follows severe bruising may be decreased by the use of phototherapy (see also Chapter 48). Ecchymoses rarely result in significant anemia.

PROGNOSIS

The ecchymoses usually resolve spontaneously within 1 week.

Subcutaneous Fat Necrosis

Subcutaneous fat necrosis is characterized by well-circumscribed, indurated lesions of the skin and underlying tissue (see also Chapter 49, Part 2).

ETIOLOGY

The cause of subcutaneous fat necrosis is uncertain, although obstetric trauma is considered a possibility. Many affected infants are large and have been delivered by forceps or after a prolonged, difficult labor involving vigorous fetal manipulation. The distribution of the lesions usually is related to the site of trauma, which explains the frequent involvement of shoulders and buttocks. Other etiologic factors that have been implicated include hypothermia, local ischemia, and intrauterine asphyxia. One suggested mechanism of pathogenesis proposes that diminished in utero circulation and mechanical pressure during labor and delivery result in vascular compromise to specific areas, which eventually causes localized fat necrosis.[16] This condition has also been described in an infant whose mother used cocaine during pregnancy. The authors postulate that cocaine may be a factor because of decreased placental perfusion with subsequent hypoxemia and alteration of the maternal and fetal pituitary-adrenal axes.[13]

PATHOLOGY

Initially, histopathologic studies reveal endothelial swelling and perivascular inflammation in the subcutaneous tissues. They are followed by necrosis of fat and a dense granulomatous inflammatory infiltrate containing foreign body-type giant cells with needle-shaped crystals resembling cholesterol.

CLINICAL MANIFESTATIONS

Necrotic areas usually appear between 6 and 10 days of age but may be noted as early as the second day or as late as the sixth week. They occur on the cheeks, neck, back, shoulders, arms, buttocks, thighs, and feet, with relative sparing of the chest and abdomen. The lesions vary in size from 1 to 10 cm; rarely, they may be more extensive. They are irregularly shaped, hard, plaquelike, and nonpitting (Fig. 28-2). The overlying skin may be colorless, red, or purple. The affected areas may be slightly elevated above the adjacent skin; small lesions may be easily moveable in all directions. There is no local tenderness or increase in skin temperature.

Marked symptomatic hypercalcemia may develop in infants with subcutaneous fat necrosis at 3 to 4 weeks of age; this has been characterized by vomiting, weight loss, anorexia, fever, somnolence, and irritability, with serum calcium levels as high as 16.2 mg/dL.[18,46] Improvement generally has occurred after intravenous hydration, furosemide, and hydrocortisone

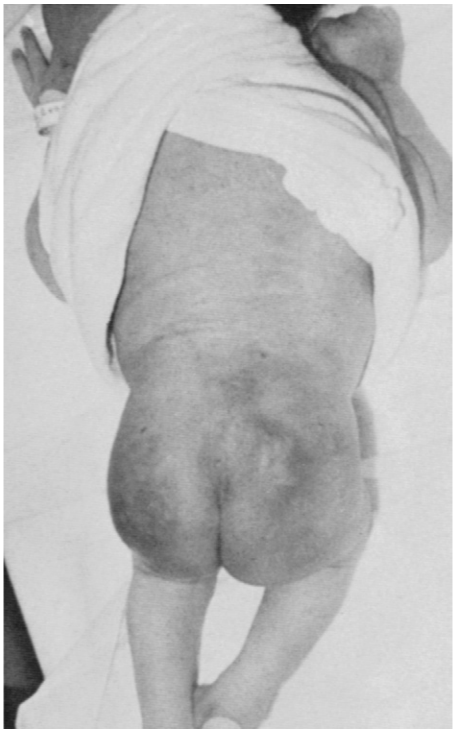

Figure 28–2. Subcutaneous fat necrosis in a 2900-g term infant delivered vaginally; pregnancy, labor, and delivery were completely uncomplicated. Note nodular lesion located on right buttock and surrounded by erythema (*darkened area*). *(Courtesy of Dr. Rajam Ramamurthy, Cook County Hospital, Chicago.)*

therapy. Investigators have suggested extrarenal production of 1,25-dihydroxyvitamin D by the granulomatous cells of fat necrosis as a possible mechanism for the hypercalcemia.[18,46]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes lipogranulomatosis and sclerema neonatorum, which carry a serious prognosis, and nodular nonsuppurative panniculitis, which is usually associated with fever, hepatosplenomegaly, and tender skin nodules.

TREATMENT

These lesions require only observation. Surgical excision is not indicated.

PROGNOSIS

The lesions slowly soften after 6 to 8 weeks and completely regress within several months. Occasionally, minimal residual atrophy, with or without small calcified areas, is observed. Affected infants should be followed closely during the first 6 weeks for potential development of hypercalcemia. It is important to treat this complication without delay to prevent central nervous system (CNS) and renal sequelae.[18]

Lacerations

Accidental lacerations may be inflicted with a scalpel during cesarean section. They usually occur on the scalp, buttocks, and thighs, but they may occur on any part of the body. If the wound is superficial, the edges may be held in apposition with butterfly adhesive strips. Deeper, more freely bleeding wounds should be sutured with the finest material available, preferably 7-0 nylon. Rarely, the amount of blood loss and depth of wound require suturing in the delivery room. After repair, the wound should be left uncovered unless it is in an area of potential soiling, such as the perineal area; in such locations, the wound should be sprayed with protective plastic. Healing is usually rapid, and the sutures may be removed after 5 days.

INJURIES TO THE HEAD

Skull

CAPUT SUCCEDANEUM

Caput succedaneum, a frequently observed lesion, is characterized by a vaguely demarcated area of edema over that portion of the scalp that was the presenting part during a vertex delivery.

Etiology

Serum or blood or both accumulate above the periosteum in the presenting part during labor. This extravasation results from the higher pressure of the uterus or vaginal wall on those areas of the fetal head that border the caput. Thus, in a left occiput transverse presentation, the caput succedaneum occurs over the upper and posterior aspect of the right parietal bone; in a right-sided presentation, it occurs over the corresponding area of the left parietal bone.

Clinical Manifestations

The soft swelling is usually a few millimeters thick and may be associated with overlying petechiae, purpura, or ecchymoses. Because of the location external to the periosteum, a caput succedaneum may extend across the midline of the skull and across suture lines. After an especially difficult labor, an extensive caput may obscure various sutures and fontanelles.

Differential Diagnosis

Occasionally, a caput succedaneum may be difficult to distinguish from a cephalhematoma, particularly when the latter occurs bilaterally. Careful palpation usually indicates whether the bleeding is external to the periosteum (a caput) or beneath the periosteum (a cephalhematoma).

Treatment

Usually no specific treatment is indicated. Rarely, a hemorrhagic caput may result in shock and require blood transfusion.

Prognosis

A caput succedaneum usually resolves within several days.

CEPHALHEMATOMA

Cephalhematoma is an infrequently seen subperiosteal collection of blood overlying a cranial bone. The incidence is 0.4% to 2.5% of live births; the frequency is higher in male infants and in infants born to primiparous mothers.

Etiology

A cephalhematoma is caused during labor or delivery by a rupture of blood vessels that traverse from skull to periosteum. Repeated buffeting of the fetal skull against the maternal pelvis during a prolonged or difficult labor and mechanical trauma caused by use of forceps in delivery have been implicated. Petrikovsky and associates[64] described seven infants in whom cephalhematoma or caput succedaneum was identified prenatally before onset of labor. Occurrence of premature rupture of membranes in five of the pregnancies suggests an etiology of fetal head compression by the uterine wall, resulting from oligohydramnios subsequent to the ruptured membranes.

Clinical Manifestations

The bleeding is sharply limited by periosteal attachments to the surface of one cranial bone; there is no extension across suture lines. The bleeding usually occurs over one or both parietal bones. Less often, it involves the occipital bones and, very rarely, the frontal bones. The overlying scalp is not discolored. Because subperiosteal bleeding is slow, the swelling may not be apparent for several hours or days after birth. The swelling is often larger on the second or third day, when sharply demarcated boundaries are palpable. The cephalhematoma may feel fluctuant and often is bordered by a slightly elevated ridge of organizing tissue that gives the false sensation of a central bony depression. In 1974, Zelson and coworkers[93] noted an underlying skull fracture in 5.4% of cephalhematomas. These fractures are almost always linear and nondepressed.

Radiographic Manifestations

Radiographic manifestations vary with the age of the cephalhematoma. During the first 2 weeks, bloody fluid results in a shadow of water density. At the end of the second week, bone begins to form under the elevated pericranium at the margins of the hematoma; the entire lesion is progressively overlaid with a complete shell of bone.

Differential Diagnosis

A cephalhematoma may be differentiated from caput succedaneum by (1) its sharp periosteal limitations to one bone, (2) the absence of overlying discoloration, (3) the later initial appearance of the swelling, and (4) the longer time before resolution. Cranial meningocele is differentiated from cephalhematoma by pulsations, an increase in pressure during crying, and the demonstration of a bony defect on a radiograph. An occipital cephalhematoma may be confused initially with an occipital meningocele and with cranium bifidum because all occupy the midline position.

Treatment

Therapy is not indicated for the uncomplicated cephalhematoma. Rarely, a massive cephalhematoma may result in blood loss severe enough to require transfusion. Significant hyperbilirubinemia also may result, necessitating phototherapy or other treatment of jaundice (see also Chapter 48). The most common associated complications are skull fracture and intracranial hemorrhage. Linear fractures do not require specific therapy, but radiographs should be taken at 4 to 6 weeks to ensure closure and to exclude formation of leptomeningeal cysts; depressed fractures require immediate neurosurgical consultation. Specific treatment of blood loss or hyperbilirubinemia or both may be indicated if there has been an intracranial hemorrhage. Routine incision or aspiration of a cephalhematoma is contraindicated because of the risk for introducing infection. Rarely, bacterial infections of cephalhematomas occur, usually in association with septicemia and meningitis. Focal infection should be suspected when a sudden enlargement of a static cephalhematoma occurs during the course of a systemic infection, with a relapse of meningitis or sepsis after treatment with antibiotics, or with the development of local signs of infection over the cephalhematoma (Fig. 28-3). Diagnostic aspiration may be indicated. If a local infection is present, surgical drainage and specific antibiotic therapy should be instituted. Osteomyelitis of the underlying skull may be a rare concurrent problem.[56,59] The diagnosis may be suggested by periosteal elevation and overlying soft tissue swelling on skull radiographs. Additional rare complications that may accompany an infected cephalhematoma and osteomyelitis include venous sinus thrombosis and cerebellar hemorrhage.[14] Magnetic resonance imaging (MRI) should be used to detect these two intracranial complications, whereas computed tomography (CT) is the best imaging modality to identify the permeative bone erosion and destruction of osteomyelitis.[14]

Prognosis

Most cephalhematomas are resorbed within 2 weeks to 3 months, depending on their size. In a few patients, calcium is deposited (Fig. 28-4), causing a bony swelling that may persist for several months and, rarely, up to several years.

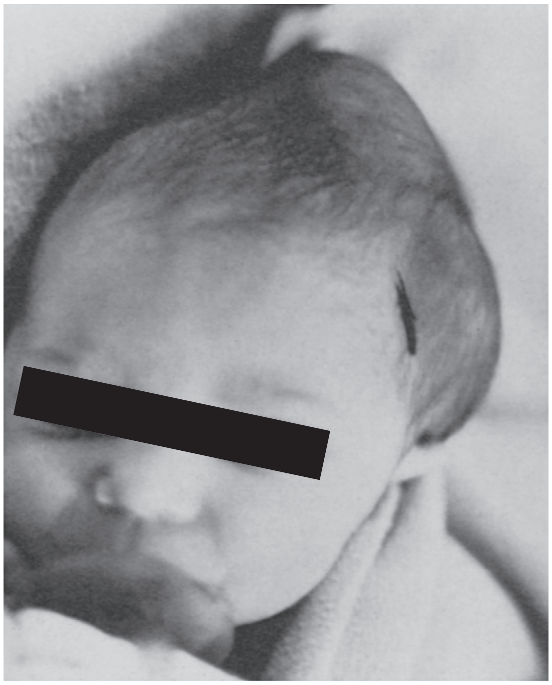

Figure 28–3. Massive, persistently enlarging cephalhematoma in a 13-day-old female infant delivered by midforceps after occiput-posterior presentation. Surgical drainage revealed 300 mL of yellowish material that cultured *Escherichia coli*.

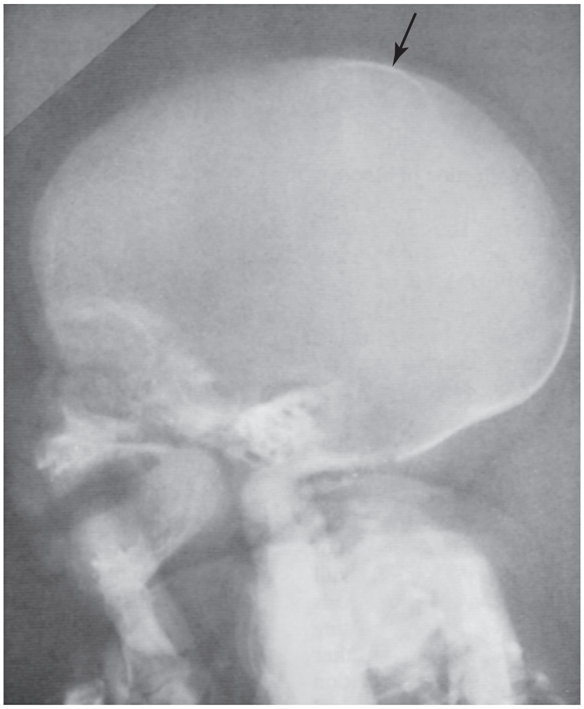

Figure 28–4. Calcified cephalhematoma (*arrow*) in left parietal region of 5-week-old girl. Infant weighed 1410 g at birth and was delivered rapidly because of prolapsed cord. Hard left parietal swelling was detected at 5 weeks by nurses during feeding.

Radiographic findings persist after the disappearance of clinical signs. The outer table remains thickened as a flat, irregular hyperostosis for several months. Widening of the space between the new shell of bone and the inner table may persist for years; the space originally occupied by the hematoma usually develops into normal diploic bone, but cystlike defects may persist at the sites of the hematoma for months or years. Rarely, a neonatal cephalhematoma may persist into adult life as a symptomless mass, the cephalhematoma deformans of Schüller.

SUBGALEAL HEMORRHAGE

Subgaleal hemorrhage is a collection of blood in the soft tissue space between the galea aponeurotica and the periosteum of the skull (Fig. 28-5). The incidence is about 4 per 10,000 deliveries, with an even higher incidence after instrumental deliveries. Ng and colleagues[61] have reported an incidence of 64 per 10,000 deliveries when vacuum extraction is performed.

Etiology

The most common predisposing factor is difficult operative vaginal delivery, particularly midforceps delivery and vacuum extraction.[87] Plauche reported that operative vaginal delivery was the most common factor in 64% of cases of subgaleal hemorrhage.[66] The risk for subgaleal hemorrhage may be reduced by use of softer silicone vacuum cups instead of the original rigid metallic ones.[9] The major risk factors include coagulopathies,[17,74] prematurity, macrosomia, fetal dystocia, precipitous labor, intrapartum hypoxia, male sex, cephalopelvic disproportion, prolonged labor, and nulliparity.[66,87]

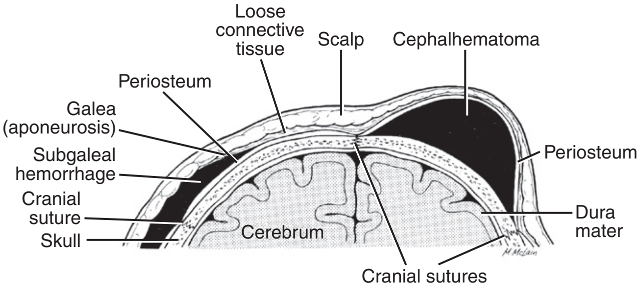

Figure 28–5. Subgaleal hemorrhage and cephalhematoma.

Mechanism of Injury

When vacuum is used, the mechanism of injury is thought to be the vacuum traction pulling the scalp away from stationary bony calvarium, thus avulsing open the subgaleal space and causing the bridging vessels to tear and bleed into the subgaleal space. The loose connective tissue of the subgaleal space is extremely expansive and extends over the entire area of the scalp. The space can accommodate the entire neonatal blood volume (250 mL or more in a term baby), leading to hypovolemic shock, disseminated intravascular coagulation, and multiple-organ failure, resulting in death in 25% of the cases.[66,88]

Clinical Manifestations

Early manifestations may be limited to pallor, hypotonia, and diffuse swelling of the scalp. The development of a fluctuating mass straddling cranial sutures, fontanelles, or both is highly suggestive of the diagnosis. Because blood accumulates beneath the aponeurotic layer, ecchymotic discoloration of the scalp is a later finding.[32] This often is associated with pitting edema and progressive posterior spread toward the neck and lateral spread around the ears, frequently displacing the ears anteriorly (Fig. 28-6). Periorbital swelling and ecchymosis also are commonly observed.[66] Eventually, hypovolemic shock and signs of cerebral irritation develop. Massive lesions can cause extracranial cerebral compression, which may lead to rapid neurologic decompensation.[5] The clinician should be aware of occasional “silent presentation,” in which a fluctuant mass is not apparent initially despite serial clinical examinations.[61] Subgaleal hemorrhage should be considered in infants who show signs of hypoperfusion and falling hematocrit after attempted or successful vacuum delivery, even in the absence of a detectable fluctuant mass.

Radiographic Manifestations

Standard radiographs of the skull may identify possible associated fractures. CT scanning may demonstrate abundant epicranial blood, parieto-occipital bone dehiscence, bone fragmentation, and posterior cerebral interhemispheric densities compatible with subarachnoid hemorrhage.[32]

Differential Diagnosis

In contrast to cephalhematoma, subgaleal hemorrhage is characterized by its more diffuse distribution, more rapid course, significant anemia, signs of CNS trauma (e.g., hypotonia, lethargy, seizures), and frequent lethal outcome.

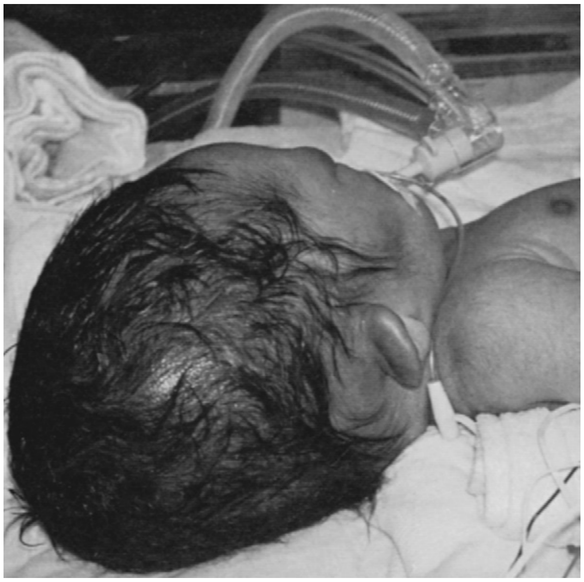

Figure 28–6. Clinical manifestations of subgaleal hemorrhage. Note anteriorly displaced ear.

Treatment

Prompt restoration of blood volume with fresh frozen plasma or blood is essential. If the bleeding continues, gentle compression wraps may be applied to the head; however, the value of this therapy is only anecdotal.[9] In the presence of continued deterioration, neurosurgery may be considered as a last resort. A bicoronal incision allows for exposure of the subgaleal space. Bipolar cauterization of any bleeding points can then be accomplished, and a drain can be left in the subgaleal space. One report[5] described a successful outcome after finger disimpaction of a large clot before insertion of a drain that released an additional 200 mL of blood over 2 days.

Prognosis

Nearly 25% of infants with subgaleal hemorrhage die.[42,66] More experience with aggressive and timely neurosurgical intervention may help to improve outcomes.

SKULL FRACTURES

Fracture of the neonatal skull is uncommon because the bones of the skull are less mineralized at birth and thus more compressible. In addition, the separation of the bones by membranous sutures usually permits enough alteration in the contour of the head to allow its passage through the birth canal without injury.

Etiology

Skull fractures usually follow a forceps delivery or a prolonged, difficult labor with repeated forceful contact of the fetal skull against the maternal symphysis pubis, sacral promontory, or ischial spine. They have also been described after an operative vaginal delivery.[39] Most of the fractures are linear. Depressed fractures almost always result from forceps application. However, they may occur spontaneously after cesarean section[25,29] or vaginal delivery without forceps. Factors that have been implicated include pressure on the fetal skull by a maternal bony prominence (e.g., sacral promontory) or uterine fibroid, a fetal hand or foot, or the body part of a twin. Occipital bone fractures usually occur in breech deliveries as a consequence of traction on the hyperextended spine of the infant when the head is fixed in the maternal pelvis.

Clinical Manifestations

Linear fractures over the convexity of the skull frequently are accompanied by soft tissue changes and cephalhematoma. Usually the infant's behavior is normal unless there is an associated concussion or hemorrhage into the subdural or subarachnoid space. Fractures at the base of the skull with separation of the basal and squamous portions of the occipital bone almost always result in severe hemorrhage caused by disruption of the underlying venous sinuses. The infant may then exhibit shock, neurologic abnormalities, and drainage of bloody cerebrospinal fluid from the ears or nose.

Depressed fractures are visible, palpable indentations in the smooth contour of the skull, similar to dents in a ping-pong ball (Fig. 28-7). The infant may be entirely free of symptoms unless there is an associated intracranial injury.

Radiographic Manifestations

The diagnosis of a simple linear or fissure fracture is seldom made without radiographs in which fractures appear as lines and strips of decreased density. Depressed fractures appear as lines of increased density. On some views, they are manifested by an inward buckling of bone with or without an actual break in continuity. Either type of fracture may be seen on only one view.

Differential Diagnosis

Occasionally, the fragments of a linear fracture may be widely separated and may simulate an open suture. Conversely, parietal foramina, the interparietal fontanelle, mendosal sutures,

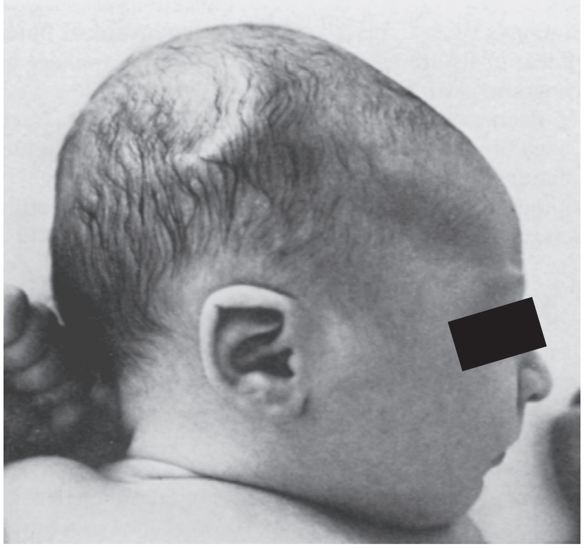

Figure 28–7. Depressed skull fracture in term male infant delivered after rapid (1-hour) labor. Infant was delivered by occiput-anterior presentation after rotation from occiput-posterior position.

and innominate synchondroses may be mistaken for fractures. In addition, normal vascular grooves, “ripple lines” that represent soft tissue folds of the scalp, and lacunar skull may be mistaken for fractures.

Treatment

Uncomplicated linear fractures over the convexity of the skull usually do not require treatment. Fractures at the base of the skull often necessitate blood replacement for severe hemorrhage and shock in addition to other supportive measures. If cerebrospinal fluid rhinorrhea or otorrhea is present, antimicrobial coverage is indicated to prevent secondary infection of the meninges.

Small (<2 cm) “ping-pong” fractures may be observed without surgical treatment. Loeser and associates[50] reported three infants with depressed skull fractures in whom spontaneous elevation of the fractures occurred within 1 day to 3½ months of age. Follow-up at 1 to 2½ years revealed normal neurologic development in all three.

Several nonsurgical methods have been described for elevation of depressed skull fractures in certain infants:

1. A thumb is placed on opposite margins of the depression, and gentle, firm pressure is exerted toward the middle. After several minutes of continuous pressure, the area of depression gradually disappears.[72]
2. A hand breast pump is applied to the depressed area. Petroleum jelly placed on the pump edges ensures a tighter seal, and gentle suction for several minutes results in elevation of the depressed bone.[77]
3. A vacuum extractor is placed over the depression, and a negative pressure of 0.2 to 0.5 kg/cm^2 is maintained for about 4 minutes.[76,84]

Because these methods are technically easier and less traumatic, they may be preferable to surgical intervention in a symptom-free infant with an isolated lesion.

Comminuted or large fractures associated with neurologic signs or symptoms should be treated by immediate surgical elevation of the indented segment to prevent underlying cortical injury from pressure. Other indications for surgical elevation include manifestations of cerebrospinal fluid beneath the galea and failure to elevate the fracture by nonsurgical manipulation.

Prognosis

Simple linear fractures usually heal within several months without sequelae. Rarely, a leptomeningeal cyst may develop from an associated dural tear, and meninges or part of the brain may protrude through the fracture. The fracture line may widen rapidly within weeks, or a large defect in the skull may be noted many months later. If detected early, the cyst may be excised successfully and brain atrophy prevented. It is therefore advisable to repeat skull radiographs within 2 to 3 months to detect early widening of the fracture line. Color Doppler imaging has been demonstrated to enhance earlier diagnosis of leptomeningeal cyst during the second week of life.[89]

Basal fractures carry a poor prognosis. When separation of the basal and squamous portions of the occipital bone occurs, the outcome is almost always fatal; surviving infants have an extremely high incidence of neurologic sequelae.

The prognosis for a depressed fracture is usually good when treatment is early and adequate. When therapy is delayed, especially with a large depression, death may occur from pressure on vital areas of the brain. Because the natural history of depressed skull fractures in neonates has not been clearly elucidated, the outcome is uncertain for infants with smaller lesions managed either by simple observation or by surgery after significant delays. Despite the apparently normal outcome in the three infants reported by Loeser and associates,[50] one cannot completely exclude the possibility that subtle neurologic sequelae may develop years later.

INTRACRANIAL HEMORRHAGE

See Chapter 40.

Face

FACIAL NERVE PALSY

Facial nerve palsy in the neonate may follow birth injury or rarely may result from agenesis of the facial nerve nucleus. The latter condition occasionally is hereditary but usually is sporadic.

Etiology

Traumatic facial nerve palsy most often follows compression of the peripheral portion of the nerve, either near the stylomastoid foramen, through which it emerges, or where the nerve traverses the ramus of the mandible. The nerve may be compressed by forceps, especially when the fetal head has been grasped obliquely. The condition also occurs after spontaneous deliveries in which prolonged pressure was applied by the maternal sacral promontory. Less frequently, injury is sustained in utero, often in association with a mandibular deformity, by the persistent position of the fetal foot against the superior ramus of the mandible. An extremely rare cause is the pressure of a uterine tumor on the nerve.

This condition may occur rarely with a simultaneous ipsilateral brachial plexus palsy, most likely secondary to compressive forces during delivery.[21] Contributing factors include prolonged second stage of labor and midforceps delivery.

A traumatic facial nerve palsy may follow a contralateral injury to the CNS, such as a temporal bone fracture, or hemorrhage, tissue destruction, or both to structures within the posterior fossa. This CNS injury is less frequent than peripheral nerve injury.

Clinical Manifestations

Paralysis is usually apparent on the first or second day but may be present at birth. It usually does not increase in severity unless considerable edema occurs over the area of nerve trauma. The type and distribution of paralysis are different in central facial paralysis compared with peripheral paralysis.

Central paralysis is a spastic paralysis limited to the lower half or two thirds of the contralateral side of the face. The paralyzed side is smooth and full and often appears swollen. The nasolabial fold is obliterated, and the corner of the mouth droops. When the infant cries, the mouth is drawn to the normal side, the wrinkles are deeper on the normal side, and movement of the forehead and eyelid is unaffected. Usually other manifestations of intracranial injury appear, most often a sixth cranial nerve palsy.

Peripheral paralysis is flaccid and, when complete, involves the entire side of the face. When the infant is at rest, the only sign may be a persistently open eye on the affected side, caused by paralysis of the orbicular muscle of the eye. With crying, the findings are the same as in a central facial nerve injury, with the addition of a smooth forehead on the involved side. Because the tongue is not involved, feeding is not affected.

A small branch of the nerve may be injured, with involvement of only one group of facial muscles. Paralysis is then limited to the forehead, eyelid, or mouth. Peripheral paralysis caused by nerve injury distal to the geniculate ganglion may be accompanied by a hematotympanum on the same side.

Differential Diagnosis

Central and peripheral facial nerve palsies must be distinguished from nuclear agenesis (Möbius syndrome). The latter frequently results in bilateral facial nerve palsy; the face is expressionless and immobile, suggesting muscle fibrosis. Other cranial nerve palsies and deformities of the ear, palate, tongue, mandible, and other bones may be associated with Möbius syndrome. Congenital absence or hypoplasia of the depressor muscle of the angle of the mouth also may simulate congenital facial palsy and has been associated with an increased incidence of other congenital anomalies.

Treatment

No specific therapy is indicated for most facial palsies. If the paralysis is peripheral and complete, initial treatment should be directed at protecting the cornea with an eye pad and instilling 1% methylcellulose drops every 4 hours. The functional state of the nerve should be followed closely. Falco and colleagues[26] proposed the following comprehensive approach:

1. Distinguish developmental from acquired lesions on the basis of the birth history and a detailed physical examination. Patients thought to have developmental palsy should be examined with radiologic and electrodiagnostic studies and brainstem evoked response as appropriate.
2. Because of the expected 90% likelihood of complete spontaneous recovery, patients should be observed for 1 year before surgical intervention is considered. If recovery is suggested by physical examination or serial electromyography, observation without surgery may be delayed until the second birthday. Infants who require surgery are best treated with decompression or neuroplasty or both.

Prognosis

Most facial palsies resolve spontaneously within several days; total recovery may require several weeks or months. Electrodiagnostic testing is beneficial in predicting recovery; repeatedly normal nerve excitability indicates a good prognosis, but decreased or absent excitability early in the course suggests a poor outlook. The subsequent appearance of muscle fibrillation potentials indicates nerve degeneration. The prognosis in surgically treated infants worsens with increasing age at treatment.

FRACTURES AND DISLOCATIONS OF FACIAL BONES

Facial bone fractures may occur during passage through the birth canal, during forceps application and delivery, and during obstetric manipulation (most often the Mauriceau maneuver for delivery of the fetal head in a breech presentation). Manipulation may result in mandibular fractures and mandibular joint damage but is rarely severe enough to cause separation of the symphysis of the mandible. Fracture of the nose may result in early respiratory distress and feeding difficulties. The most frequent nasal injury is dislocation of the cartilaginous part of the septum from the vomerine groove and columella. This may result from intrauterine factors such as a uterine tumor or persistent pressure on the nose by fetal small parts or during delivery from pressure on the nose by the symphysis pubis, sacral promontory, or perineum. The presence of nasal septal dislocation may be differentiated from the more common normal variant of a misshapen nose by a simple compression test, in which the tip of the nose is compressed[19] (Fig. 28-8). In the presence of septal dislocation, the nostrils collapse, and the deviated septum becomes more apparent; in the normal nose, no nasal deviation occurs with compression.

Infants who sustain nasal trauma during the birth process may demonstrate stridor and cyanosis, even in the absence of septal dislocation. Miller and coworkers[57] noted high nasal resistance in three such infants, of whom only one was found to have septal dislocation. The authors postulated the presence of edema and narrowed nasal passages from compression forces on the midface during delivery. The problem may be exaggerated by repeated nasal suctioning or transnasal bronchoscopy. These procedures and oral feeding should be avoided until the infant reestablishes normal nasal ventilation. Transcutaneous oxygen and carbon dioxide tensions and pulse oximetry measurements are useful in monitoring these infants.

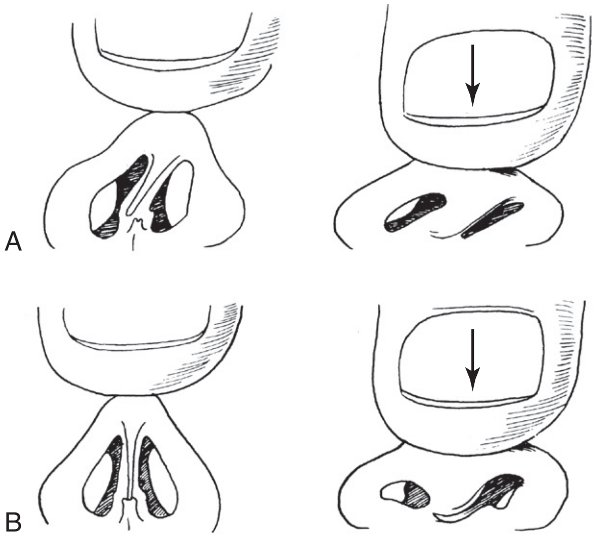

Figure 28–8. Result of finger compression (**A**) when nasal septum is dislocated. Normal septal relationship (**B**) results in no nasal deviation with pressure. (*Modified from Daily W, et al: Nasal septal dislocation in the newborn,* Mo Med *74:*381, *1977.)*

Treatment

Fractures of the maxilla, lacrimal bones, and nose warrant immediate attention because they unite quickly, with fixation in 7 to 10 days. Nasal trauma frequently requires extensive surgery, so the pediatrician should request immediate consultation with a surgeon with expertise in nasal surgery. While waiting, the pediatrician should provide an oral airway to relieve respiratory distress. Often the surgeon can grasp the traumatized nose and elevate and remold it manually, relieving the respiratory distress. Fractures of the septal cartilage also may be reduced by simple manual remolding, but most are associated with hematomas that should be promptly incised and drained. The surgeon can visualize the deformity with an infant nasal speculum, place a septal elevator in the nose, and guide the septal cartilage into the vomerine groove; an audible and palpable click indicates return of the septum into position.[82]

Early reduction and immobilization also are advised for a displaced fracture of the mandible because rapid, firm union may occur as early as 10 to 14 days. Usually, adequate alignment can be achieved with an acrylic mandibular splint and circum-mandibular wires, which are maintained in place for 3 weeks. In more severe cases with canting of the mandibular alveolar ridge, perialveolar wires below the infraorbital rims have been used with excellent results. This procedure can prevent canted occlusion and possible facial asymmetry as the child grows, thus avoiding later extensive and costly reconstructive surgery.[69]

Prognosis

If the fracture is reduced and fixated within a few days, rapid healing without complication is the usual course. If treatment is inadequate, missed, or delayed, subsequent developmental deformities are common. Ankylosis of the mandible in the second year of life is thought to result from birth trauma to the temporomandibular joint. A young child has been described with unilateral mandibular hypoplasia, which was thought to have resulted from fibrous ankylosis caused by perinatal trauma to the condylar cartilage of the ipsilateral temporomandibular joint.[10] Other deformities may not become apparent until adolescence or young adulthood.

Eyes

(See also Chapter 53)

Mechanical trauma to various regions of the neonatal eye usually occurs during abnormal presentation, in dystocia from cephalopelvic disproportion, or as a result of inappropriate forceps placement in normal deliveries. Most of the injuries are self-limited and mild and require no specific treatment.

EYELIDS

Edema, suffusion, and ecchymoses of the eyelids are common, especially after face and brow presentations or forceps deliveries. Severely swollen lids should be forced open by an ophthalmologist for examination of the eyeball; retractors may be necessary. These findings usually resolve within a week without treatment, although an infant has been reported with totally everted upper eyelids that required suturing for 4 days before they would remain in the normal position.[71] Some believe that these injuries represent a possible cause of congenital ptosis.

A less common injury is laceration, including disruption of the lacrimal canaliculus. This has been associated with multiple upper-eyelid lacerations, including a full-thickness vertical wound lateral to the punctum and a full-thickness laceration through the lower eyelid with transection of the canaliculus after a low forceps delivery. Microsurgical repair of the lacrimal system and eyelids, including lacrimal intubation with a silicone stent, has been successful. Follow-up at 14 months revealed normal tear drainage with no amblyopia or residual deformity.[38]

An infant has been reported with superficial eyelid lacerations caused by an internal fetal monitoring spiral electrode.[48] At delivery, the electrode was attached to the eyelid. Marked facial edema related to brow presentation apparently obscured the lacerations until 14 hours of age, when much of the edema had resolved. Periorbital edema was believed to have protected the infant from more serious injury to the eyelid and globe.

Lagophthalmos, the inability to close an eye, is an occasional finding thought to result from facial nerve injury by forceps pressure. It usually is unilateral. The exposed cornea should be protected by an eye pad and methylcellulose drops instilled every 4 hours. The condition usually resolves within a week.

ORBIT

Orbital hemorrhage and fracture may follow direct pressure by the apex of one forceps blade, most often in high forceps extractions. In most instances, death occurs immediately. Surviving infants demonstrate traumatic eyelid changes, disturbances of extraocular muscle movements, and exophthalmos. The presence of the latter two findings warrants immediate ophthalmologic consultation. Subsequent management also may require neurosurgical and plastic surgery consultations.

SYMPATHETIC NERVOUS SYSTEM

Horner syndrome, resulting from cervical sympathetic nerve trauma, frequently accompanies lower brachial plexus injury (see later in this chapter). The syndrome consists of miosis, partial ptosis, slight enophthalmos, and anhidrosis of the ipsilateral side of the face. Although small, the pupil reacts to light. The presence of neurologic signs indicating brachial plexus injury helps distinguish this syndrome from intracranial hemorrhage as a cause of anisocoria. Pigmentation of the ipsilateral iris is frequently delayed to several months of age; occasionally, pigmentation never occurs. Resolution of other signs of the syndrome depends on whether the injury to the nerve is transient or permanent.

SUBCONJUNCTIVAL HEMORRHAGE

Subconjunctival hemorrhage, characterized by bright red patches on the bulbar conjunctiva, is a relatively common finding in the neonate. It may be found after a difficult delivery but often is noted after easy, completely uncomplicated deliveries. This finding is considered to result from increased venous pressure in the infant's head and neck, produced by obstruction to venous return consequent to compression of the fetal thorax or abdomen by uterine contractions during labor. If the infant is otherwise well, management consists of reassuring the parents. The blood is usually absorbed within 1 to 2 weeks. As the blood pigments break down and are absorbed, the color changes from bright red to orange and yellow.

EXTERNAL OCULAR MUSCLES

Injury involving the external ocular muscles may result from direct trauma to the cranial nerve (in the form of compression or surrounding hemorrhages) or from hemorrhage into the muscle sheath, with subsequent fibrosis. The sixth cranial nerve (abducens) is the most frequently injured cranial nerve because of its long intracranial course; the result is paralysis of the lateral rectus muscle. This injury may follow a tentorial laceration with extravasation of a small amount of blood around the intracranial portion of the nerve. The involvement may be mild and transient; internal strabismus noted at birth may resolve gradually within 1 to 2 months. The seventh cranial nerve may be injured simultaneously with the sixth nerve by compression with forceps. Improvement in lateral gaze of the affected eye may appear within 1 to 2 months. Alternate patching of either eye in the severely affected infant maintains visual acuity until, with time, maximal improvement has occurred. At 6 months, the degree of nerve regeneration may be evaluated. Some infants subsequently require surgical repair of the strabismus.

Fourth cranial nerve (trochlear) palsy occurs infrequently. It may follow small brainstem hemorrhages with nuclear damage. The affected muscle is the superior oblique, which mainly turns the eye inferiorly and medially. This condition is difficult to identify in the newborn infant. Surgical correction may be necessary later.

Third cranial nerve (oculomotor) palsy, when complete, causes paralysis of the inferior oblique and medial, superior, and inferior rectus muscles. This results in ptosis, a dilated fixed pupil, and outward and downward deviation of the eye, with inability to adduct or elevate up and in or up and out or to depress down and out. This palsy also may occur in partial form, with or without pupillary involvement. Partial palsies may recover function spontaneously within several months, whereas complete palsies usually require surgical intervention.

OPTIC NERVE

The optic nerve may be injured directly by a fracture in the region of the optic canal or from a shearing force on the nerve, with resultant hemorrhage into the nerve sheath. The latter injury seldom is recognized because of the more apparent and severe changes in the sensorium. Occasionally, a fracture through the optic foramen results in formation of callus, which slowly compresses the nerve. A difficult forceps delivery is a frequent preceding event. If optic nerve injury is not diagnosed within several hours with prompt surgical intervention, irreversible damage is likely. The result is optic atrophy and blindness. This is characterized by a blue-white optic disc, in contrast to the grayish disc of the normal neonate. In primary optic atrophy (e.g., that caused by birth trauma), the disc margin is well defined, and fine vessels are rarely present in the disc tissue. In secondary atrophy, the disc margin is blurred; a central gray area and evidence of intraocular disease are present.

CORNEA

A diffuse or streaky haziness of the cornea is relatively common. This is usually caused by edema related to the birth process but also may follow use of a silver nitrate solution more concentrated than 1%. The haziness usually disappears in 7 to 10 days. When it persists, a rupture of the Descemet membrane has probably occurred, usually because of malpositioning of forceps at delivery. The consequence of a ruptured Descemet membrane is a leukoma or diffuse white opacity of the cornea. This results from interstitial damage of the substantia propria by fluids entering through the tear in the membrane. These leukomas are often permanent and, despite patching of the contralateral eye and use of glasses, are accompanied by a high incidence of amblyopia and strabismus.

A ruptured Descemet membrane has been reported after a prolonged delivery in which low forceps were used after unsuccessful attempts at vacuum extraction.[83] Because of significant corneal astigmatism at 2 months, a gas-permeable hard contact lens was applied. Patching of the contralateral eye was continued. Assessment of visual acuity at 13 months, with the use of spatial frequency sweep visual evoked potentials, demonstrated an excellent visual result.

INTRAOCULAR HEMORRHAGE

Trauma at birth may result in retinal hemorrhage, hyphema, or vitreous hemorrhage, with retinal hemorrhage the most common. The cause is most likely compression of the fetal head, resulting in venous congestion. The fetal head is compressed two to four times more forcefully than other fetal parts during the second stage of labor. Retinal hemorrhage is more common in primiparous deliveries and after forceps or vacuum extraction; it is rare after cesarean section. It may occur in normal deliveries. The most common lesion is the flame-shaped or streak hemorrhage found mainly near the disc and sparing the macula and extreme periphery; it usually disappears within 1 to 3 days (occasionally 5 days) with no residual effects. Rarely, hemorrhages may take as long as 21 days to resolve. It is critical to identify birth-related retinal hemorrhages and to document their presence on the infant's chart, in order to avoid subsequent suspicion of child abuse. Retinal hemorrhages may reduce the resolving power of the macula, either bilaterally to produce nystagmus or unilaterally to produce amblyopia, which may not always respond to prolonged covering of the fixing eye with improvement of the amblyopic eye.

Hyphemas and vitreous hemorrhages usually result from misplacement of forceps and often are associated with ruptures of the Descemet membrane. One infant has been described in whom a hyphema developed in one eye after spontaneous delivery.[67] The hyphema usually is clear of gross blood within 5 days; during this time, the infant should be handled gently and fed frequently to minimize crying and agitation. If blood persists or secondary hemorrhage occurs, systemic administration of acetazolamide (Diamox) and surgical removal of blood may be necessary.

Vitreous hemorrhage is manifested by large vitreous floaters, blood pigment seen with the slit lamp, and an absent red reflex. The prognosis is guarded; if resolution does not occur in 6 to 12 months, surgical correction should be considered.

Ears

The proximity of ears to the site of application of forceps makes them susceptible to injury at birth. Most of the injuries are mild and self-limited, but serious injuries may occur because of slipping or misplacement of forceps (Fig. 28-9).

ABRASIONS AND ECCHYMOSES

Abrasions must be cleansed gently to minimize the risk for secondary infection. Ecchymoses, if extensive and involving other areas of the body, may result in hyperbilirubinemia.

HEMATOMAS

Hematomas of the external ear, if not treated promptly, liquefy slowly, followed by early organization and development of cauliflower ear. Wide incision and evacuation of the hematoma may be indicated.

LACERATIONS

Lacerations of the auricle may be repaired by the pediatrician if they are superficial and involve only skin. After thorough cleansing and draping, the wound edges are sutured with interrupted 6-0 or 7-0 nylon sutures, with exact edge-to-edge approximation. If the laceration involves cartilage, surgical consultation should be obtained because of the tendency toward postoperative perichondritis, which is refractory to treatment and leads to subsequent deformities. A sterile field and more meticulous presurgical preparation are essential. A contour pressure dressing is applied postoperatively.

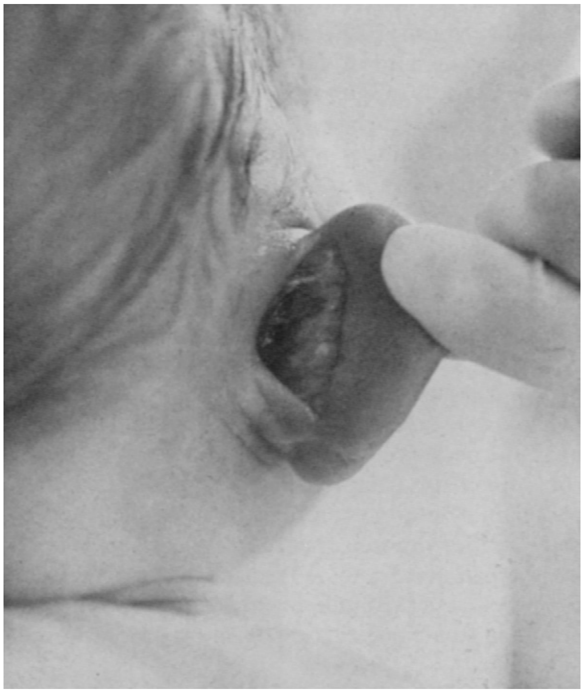

Figure 28–9. Extensive avulsion and laceration of auricle in term infant, resulting from forceful traction of misplaced forceps.

VOCAL CORD PARALYSIS

Unilateral or bilateral paralysis of the vocal cords is uncommon in the neonate.

Etiology

Unilateral paralysis may be a consequence of excessive traction on the head during a breech delivery or lateral traction with forceps in a cephalic presentation. The recurrent laryngeal branch of the vagus nerve in the neck is injured. The left side is involved more often because of this nerve's lower origin and longer course in the neck. Bilateral paralysis may be caused by peripheral trauma involving both recurrent laryngeal nerves, but more frequently, it is caused by a CNS insult such as hypoxia or hemorrhage involving the brainstem.

Clinical Manifestations

An infant with a unilateral paralysis may be completely free of symptoms when resting quietly, but crying is usually accompanied by hoarseness and mild inspiratory stridor. When associated with difficulty in feeding and clearing secretions, concurrent involvement of the 12th (hypoglossal) cranial nerve should be suspected, particularly if the tongue on the ipsilateral side does not protrude and demonstrates fasciculations. Hypoglossal paralysis also has been described in association with ipsilateral upper brachial plexus injury.[35] Affected infants demonstrate difficulty in sucking, with swelling and immobility of the affected side of the tongue. This 12th cranial neuropathy can be confirmed by concentric needle electromyography of the tongue.[33] Bilateral paralysis results in more severe respiratory symptoms. At birth, the infant may have difficulty in establishing and maintaining spontaneous respiration; later, dyspnea, retractions, stridor, cyanosis, or aphonia may develop.

Differential Diagnosis

Unilateral paralysis of the vocal cords must be distinguished from congenital laryngeal malformations that produce neonatal stridor. A history of difficult delivery, especially involving excessive traction on the fetus, may suggest laryngeal paralysis; previously, the diagnosis was confirmed only by direct laryngoscopic examination. The availability of the flexible fiberoptic laryngoscope at the bedside has facilitated earlier diagnosis without disrupting the infant's environment. Serial examinations to monitor progress also can be conducted with ease because the infant need not be transported to the operating room.

Bilateral paralysis also must be distinguished from a number of causes of respiratory distress in the neonate (see Chapter 44, Part 5); stridor should suggest the larynx as the site of disturbance. Direct or flexible fiberoptic laryngoscopy is necessary to establish the diagnosis.

Treatment

Infants with unilateral paralysis should be observed closely until there is evidence of improvement. Gentle handling and frequent small feedings aid in keeping the infant quiet and minimizing the risk for aspiration. Bilateral paralysis necessitates immediate tracheal intubation to establish an airway. Tracheostomy is required subsequently in most patients. Laryngoscopic examinations then should be performed at intervals to look for evidence of return of vocal cord function; early extubation may be attempted if complete return occurs within a short time.

Prognosis

Unilateral paralysis usually resolves rapidly without treatment, and complete resolution occurs within 4 to 6 weeks. Glossolaryngeal paralysis or paresis due to birth injury should resolve spontaneously by 6 months of age.[33] Recognition of this subtle condition is important for two reasons. First, its self-limited course is encouraging, thus avoiding needless alarm in the parents with concern about more ominous conditions such as Werdnig-Hoffmann disease. Second, unnecessary invasive and aggressive procedures can be avoided.

The prognosis for bilateral paralysis is more variable. If untreated, a funnel deformity may develop in the lower sternal area; this may appear as early as the 15th day of life. After tracheostomy, a decrease in the severity of the deformity may occur within several weeks. Some of the affected infants subsequently regain normally shaped chests; others may have residual fixed depressions, occasionally severe enough to require surgical correction. The recovery of vocal cord function varies in time and degree. Some infants may show partial recovery within a few months, with several years elapsing before complete movement of the cords is restored. Other infants who have been followed for years show no improvement. Bilateral paralysis of central origin may improve completely if it is caused by cerebral edema or hemorrhage that rapidly resolves.

INJURIES TO THE NECK, SHOULDER GIRDLE, AND CHEST

Fracture of the Clavicle

(See also Chapter 54)

The clavicle is the most frequently fractured bone during labor and delivery. Most clavicular fractures are of the greenstick type, but occasionally the fracture is complete.

ETIOLOGY

The major causes of clavicular fractures are difficult delivery of the shoulders in vertex presentations and extended arms in breech deliveries. Vigorous, forceful manipulation of the arm and shoulder usually has occurred. However, fracture of the clavicle may also occur in infants after apparently normal labor and delivery.[44,63] It has been suggested that some fetuses may be more vulnerable to spontaneous birth trauma secondary to forces of labor, maternal pelvic anatomy, and in utero fetal position.[63]

CLINICAL MANIFESTATIONS

Most often a greenstick fracture is not associated with any signs or symptoms but is first detected after the appearance of an obvious callus at 7 to 10 days of life. Thus, most neonatal clavicular fractures are diagnosed at discharge or at the first follow-up visit.[43] Complete fractures and some greenstick fractures may be apparent shortly after birth; movement of the arm on the affected side is decreased or absent. Deformity and, occasionally, discoloration may be visible over the fracture site with obliteration of the adjacent supraclavicular depression as a result of sternocleidomastoid muscle spasm. Passive movement of the arm elicits cries of pain from the infant. Palpation reveals tenderness, crepitus, and irregularity along the clavicle. Moro reflex on the involved side is characteristically absent. Radiographs confirm the diagnosis of fracture.

DIFFERENTIAL DIAGNOSIS

A similar clinical picture of impaired movement of an arm with an absent Moro reflex may follow fracture of the humerus or brachial palsy. The fracture is confirmed by radiographs; palsy is accompanied by additional clinical findings. Rarely an infant may present with a congenital pseudoarthrosis of the clavicle, which may be difficult to distinguish from a fracture. Pseudoarthrosis classically appears as a painless lump on the clavicle, with no associated tenderness nor limitation of mobility of the shoulder and arm. Radiography reveals disruption of the affected clavicle, with enlargement of the end of the bone. The etiology is uncertain. Recommended treatment options include observation only or surgical excision of the cartilaginous cap at about 4 or 5 years of age, followed by alignment of bone fragments and, if necessary, bone grafting or internal fixation.[70]

TREATMENT

Therapy is directed toward minimizing the infant's pain. The affected arm and shoulder should be immobilized with the arm abducted more than 60 degrees and the elbow flexed more than 90 degrees. A callus forms, and pain usually subsides by 7 to 10 days, when immobilization may be discontinued.

PROGNOSIS

Prognosis is excellent, with growth resulting in restoration of normal bone contour after several months.

Fracture of Ribs

Rib fractures related to labor and delivery are exceedingly rare.

ETIOLOGY

Risk factors are similar to those related to fracture of the clavicle, including macrosomia, a primigravida mother, shoulder dystocia, and delivery by midforceps or vacuum extraction.

CLINICAL MANIFESTATIONS

Specific clinical manifestations are often absent, making diagnosis difficult, unless a chest radiograph is obtained for other reasons, including suspected clavicular fracture (Fig. 28-10), respiratory distress, or cyanosis.

MECHANISM OF INJURY

This injury is initiated when the anterior shoulder is impacted behind the symphysis pubis, with the other shoulder attempting to descend into the posterior compartment of the pelvis (Fig. 28-11). This results in compression forces on the fetal arms and thorax, leading to spontaneous rib fractures on the same side as the posterior shoulder (Fig. 28-12).

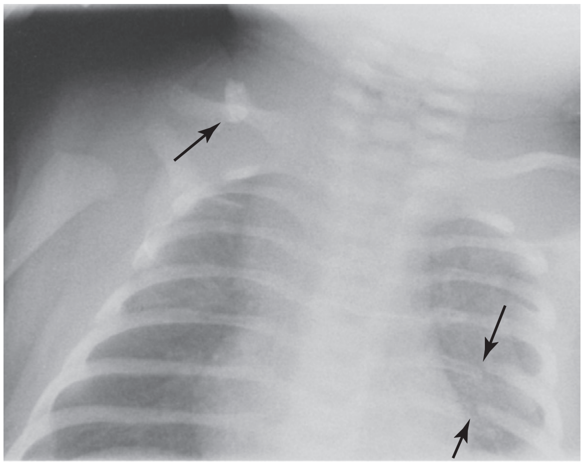

Figure 28–10. Chest radiograph of a 4905-g girl delivered by midforceps after right shoulder dystocia. On the 11th day, a prominent mass was noted in the right midclavicular region. Radiograph reveals a right midclavicular fracture (*top left arrow*) with slight superior angulation and incidental fractures of left fifth and sixth ribs (*bottom right arrows*). (*From Mangurten HH, et al: Incidental rib fractures in a neonate,* Neonat Intensive Care *12:15, 1999.)*

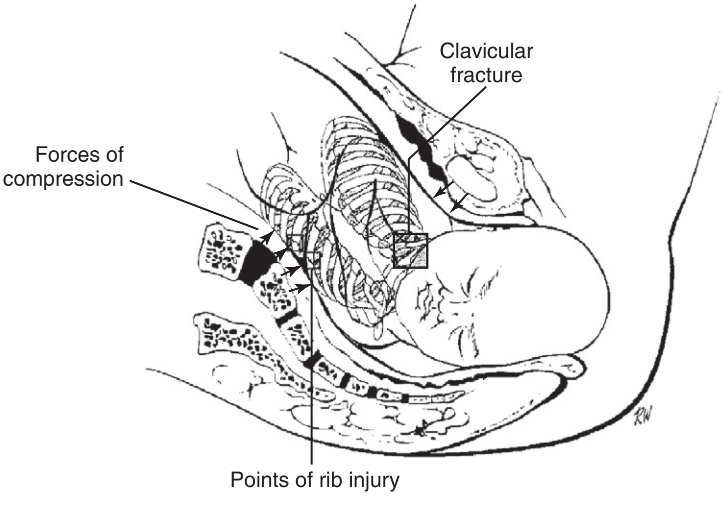
Figure 28–12. Diagram of fetus, illustrating compression forces on the fetal arms and thorax, which results in spontaneous fractures of right clavicle and left fifth and sixth ribs (*arrows*). (*From Mangurten HH, et al: Incidental rib fractures in a neonate,* Neonat Intensive Care *12:15, 1999.)*



TREATMENT

No specific treatment is required. However, it is extremely important to document this injury immediately after birth to avoid later unwarranted accusation of parents or other caretakers for suspicion of child abuse.

PROGNOSIS

Prognosis is excellent, with spontaneous healing within several months.

Brachial Palsy

(See also Chapter 54)

Brachial palsy is a paralysis involving the muscles of the upper extremity that follows mechanical trauma to the spinal roots of the fifth cervical through the first thoracic nerves (the brachial plexus) during birth. Three main forms occur, depending on the site of injury:

1. Duchenne-Erb, or upper arm, paralysis, which results from injury of the fifth and sixth cervical roots and is by far the most common;
2. Klumpke, or lower arm, paralysis, which results from injury of the eighth cervical and first thoracic roots and is extremely rare; and
3. Paralysis of the entire arm, which occurs slightly more often than the Klumpke type.

ETIOLOGY

Many cases of brachial palsy follow a prolonged and difficult labor culminating in a traumatic delivery. The affected infant is frequently large, relaxed, and asphyxiated and thereby vulnerable to excessive separation of bony segments, overstretching, and injury to soft tissues. Injury of the fifth and sixth cervical roots may follow a breech presentation with the arms extended over the head; excessive traction on the shoulder in the delivery of the head may result in stretching of the plexus. The same injury may follow lateral traction of the head and neck away from one of the shoulders during an attempt to deliver the shoulders in a vertex presentation, particularly during a vacuum extraction[60] and after shoulder dystocia.[27] More vigorous traction of the same nature results in paralysis of the entire arm. The mechanism for isolated lower arm paralysis is uncertain; it is thought to result from stretching of lower plexus nerves under and against the coracoid process of the scapula during forceful elevation and abduction of the arm. Excessive traction on the trunk during a breech delivery may result in avulsion of the lower roots from the cervical cord. In most patients, the nerve sheath is torn, and the nerve fibers are compressed by the resultant hemorrhage and edema. Less often the nerves are completely ruptured and the ends severed, or the roots are avulsed from the spinal cord with injury to the spinal gray matter.

Some authorities suggest that twisting and extension of the fetal head during the cardinal movements of labor and during delivery contribute to the occurrence of brachial palsy.[75] An increasing number of reports have described "no shoulder" brachial plexus palsy unrelated to excessive traction during delivery.[30,63] Some experts have suggested an intrauterine insult preceding labor, such as compression by uterine tumors or maternal pelvic bony prominences.[30] One study, which confirmed the well-known association of shoulder dystocia and brachial plexus injury in macrosomic infants, also identified an increased incidence of other malpresentations in low- and normal-birthweight infants with brachial plexus injury.[31] A recent report has described an infant with brachial palsy following vaginal delivery with no shoulder dystocia, no delay between delivery of the head and the body, no physician traction during the delivery, and no fundal pressure.[49] A recent large epidemiologic study revealed that 54% of infants had no identifiable risk factors.[27]

CLINICAL MANIFESTATIONS

Clinical manifestations may be understood in relation to depiction of the brachial plexus (Fig. 28-13).[65] The infant with upper arm paralysis holds the affected arm in a characteristic position, reflecting involvement of the shoulder abductors and external rotators, forearm flexors and supinators, and wrist extensors. The arm is adducted and internally rotated, with extension at the elbow, pronation of the forearm, and flexion of the wrist. When the arm is passively abducted, it falls limply to the side of the body. Moro, biceps, and radial reflexes are absent on the affected side. There may be some sensory deficit on the radial aspect of the arm, but this is difficult to evaluate in the neonate. The grasp reflex is intact. Any signs of respiratory distress may indicate an accompanying ipsilateral phrenic nerve root injury (see following section).

Lower arm paralysis involves the intrinsic muscles of the hand and the long flexors of the wrist and fingers. The hand is paralyzed, and voluntary movements of the wrist cannot be made. The grasp reflex is absent; the deep tendon reflexes are intact. Sensory impairment may be demonstrated along the ulnar side of the forearm and hand. Frequently, dependent edema and cyanosis of the hand and trophic changes in the fingernails develop. After some time, there may be flattening and atrophy of the intrinsic hand muscles. Usually an ipsilateral Horner syndrome (ptosis, miosis, and enophthalmos) also is present because of injury involving the cervical sympathetic fibers of the first thoracic root. Often this is associated with delayed pigmentation of the iris, sometimes of more than 1 year's duration.

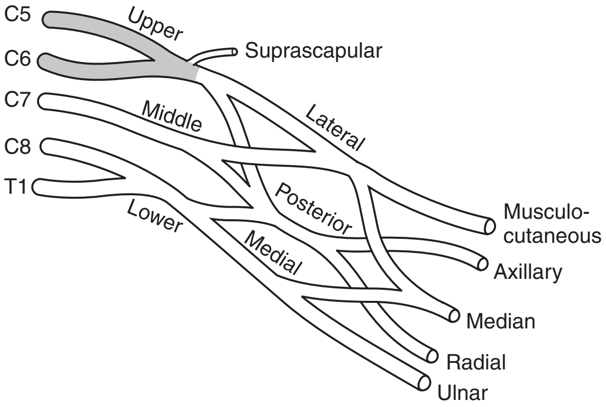


Figure 28–13. Simplified schematic diagram of brachial plexus, indicating spinal nerves of origin, trunks, cords, and major peripheral nerves. *Shaded area* signifies the portion of the plexus affected in Erb palsy. *(Courtesy of Dr. Joseph H. Piatt Jr., St. Christopher's Hospital for Children, Philadelphia, Pa.)*

When the entire arm is paralyzed, it is usually completely motionless, flaccid, and powerless, hanging limply to the side. All reflexes are absent. The sensory deficit may extend almost to the shoulder.

DIFFERENTIAL DIAGNOSIS

The presence of a flail arm in a neonate may be caused by cerebral injury or by a number of injuries about the shoulder. Cerebral injury is usually associated with other manifestations of CNS injury. A careful radiographic study of the shoulder, including an examination of the lower cervical spine, clavicle, and upper humerus, should be made to exclude tearing of the joint capsule, fracture of the clavicle, and fracture, dislocation, or upper epiphyseal detachment of the humerus. Posterior dislocation of the humeral head may be difficult to identify with standard radiographs. Torode and Donnan[86] have used CT scans to demonstrate that posterior dislocation is more common than previously believed. Hunter and coworkers[41] reported an infant in whom a posterior dislocation was uncertain with standard radiographs. Ultrasonography clearly revealed a posterior dislocation. Because posterior dislocation will complicate resolution of the palsy, ultrasonographic evaluation should be considered early in the management of these infants.

TREATMENT

The basic principle of treatment historically has been conservative, with initial emphasis on prevention of contractures while awaiting recovery of the brachial plexus. This approach has been replaced by a more comprehensive program that combines initial conservative management with closer follow-up and earlier decision regarding surgical

intervention. This is best represented by the care plan developed by Shenaq and colleagues[81] (Fig. 28-14).

This approach is initiated with a thorough and complete physical examination that includes careful palpation of the sternocleidomastoid muscle for contracture or pseudotumor; inspection for fractures of the clavicle, humerus, or ribs; observation for abdominal asymmetry, which could indicate paralysis of the hemidiaphragm; and assessment for ocular asymmetry, which may indicate associated Horner syndrome.

Ancillary investigations, including CT or myelography and MRI, could be helpful in detecting possible avulsions. Electromyography has been unreliable in predicting extent of damage.

Some infants may demonstrate discomfort because of a painful traumatic neuritis affecting the brachial plexus. If no discomfort is apparent and other lesions as noted earlier are ruled out, early passive range-of-motion exercises, particularly involving the elbow and wrist, should be instituted. Because of shorter nursery stays, the mother should receive early demonstration and written instructions describing these exercises. She should then begin to work with the infant under the guidance of the therapy staff. Exercises include shoulder rotation, elbow flexion and extension, wrist flexion and extension, finger flexion and extension, and thumb abduction, adduction, and opposition. The infant should be reevaluated every month. If improvement in deltoid, biceps, and triceps function has not occurred by the third month of life, functional outcome without surgery is unlikely. Consequently, a decision for surgery should be made by the end of the third month, followed by primary brachial plexus exploration during the fourth month.

Initial surgical intervention beyond 12 months of age at the level of the cervical root alone has resulted in disappointing outcomes. However, when infants referred at this age have been offered a combined cervical root and infraclavicular exploration with neurolysis, graph reconstruction, and nerve transfer of appropriate elements in both anatomic compartments, improved outcomes have been noted. Blaauw and Slooff have reported their experience with transfer of pectoral nerves to the musculocutaneous nerve in 25 patients, 22 of whom had upper root avulsions.[11] Seventeen patients, including one who went to surgery at 3 months of age, had excellent outcomes, five had fair outcomes, and two were considered treatment failures.

The initial surgical therapy may include a team of neurosurgeons, plastic surgeons, and physiatrists who collaborate in the exploration, evaluation, and repair of the injury. This aggressive approach has resulted in up to 90% of patients demonstrating useful function of muscle groups above the elbow. Function below the elbow has been characterized by 50% to 70% recovery because of the increased distance required for nerve regeneration.

PROGNOSIS

Continued close follow-up includes serial evaluation of shoulder, elbow, forearm, wrist, finger, and thumb function. Based on the child's progress over time, a decision is made regarding further treatment. Physical therapy is continued until there is no further progress or the deficit is debilitating. For the infant who continues to demonstrate lack of improvement in certain muscle groups, secondary surgical reconstruction is available, with a variety of options depending on the individual deficit. In summary, the infant who does not improve spontaneously now has increased hope for recovery owing to advances in microsurgery and nerve transfer techniques.

Although most (93% to 95%) infants achieve return of function with conservative management, the remainder with persistent deficits may go on to development of long-term severe handicaps of the affected extremity. Early treatment offers significant improvement for about 90% of these children. Later treatment reduces this number to 50% to 70%. To avoid missing the window of opportunity for timelier and more successful treatment, infants with brachial plexus palsy should be referred to centers that have an established comprehensive program for the broad spectrum of infants with this condition.

Phrenic Nerve Paralysis

(See also Chapter 44, Part 5)

Phrenic nerve paralysis results in diaphragmatic paralysis and rarely occurs as an isolated injury in the neonate. Most injuries are unilateral and are associated with an ipsilateral upper brachial plexus palsy.

ETIOLOGY

The most common cause is a difficult breech delivery. Lateral hyperextension of the neck results in overstretching or avulsion of the third, fourth, and fifth cervical roots, which supply the phrenic nerve.

CLINICAL MANIFESTATIONS

The first sign may be recurrent episodes of cyanosis, usually accompanied by irregular and labored respirations. The respiratory excursions of the involved side of the diaphragm are largely ineffectual, and the breathing is therefore almost completely thoracic, so that no bulging of the abdomen occurs with inspiration (Fig. 28-15A and B). The thrust of the diaphragm, which often may be felt just under the costal margin on the normal side, is absent on the affected side. Dullness to percussion and diminished breath sounds are found over the affected side. In a severe injury, tachypnea, weak cry, and apneic spells may occur.

RADIOGRAPHIC MANIFESTATIONS

Radiographs taken during the first few days may show only slight elevation of the affected diaphragm, occasionally so subtle that it may be considered normal. Additional films show the more apparent elevation of the diaphragm, with displacement of the heart and mediastinum to the opposite side (see Fig. 28-15C). Frequently, areas of atelectasis appear bilaterally. Early diagnosis can be confirmed by real-time ultrasonographic examination of the diaphragm, which reveals abnormal motion of the affected hemidiaphragm. This procedure provides the added advantage of availability at the bedside. Fluoroscopy should be reserved for the equivocal case. In still questionable cases, diagnosis can be further enhanced by transvenous electrical stimulation of the phrenic nerve.

DIFFERENTIAL DIAGNOSIS

Careful physical examination should allow differentiation among CNS, cardiac, and pulmonary causes of neonatal respiratory distress. The diagnosis can be confirmed by fluoroscopy and electrical stimulation of the phrenic nerve.

TREATMENT

Most infants require only nonspecific medical treatment. The infant should be positioned on the involved side, and oxygen should be administered for cyanosis or hypoxemia. Intravenous fluids may be necessary for the first few days. If the infant begins to show improvement, progressive oral or gavage feedings may be started. Antibiotics are indicated if pneumonia occurs.

Infants with more severe respiratory distress, particularly those with bilateral phrenic nerve palsy, may require assisted ventilation shortly after delivery. de Vries Reilingh and associates[22] have reviewed their experience with 23 infants who incurred phrenic nerve injury as neonates. Infants who had

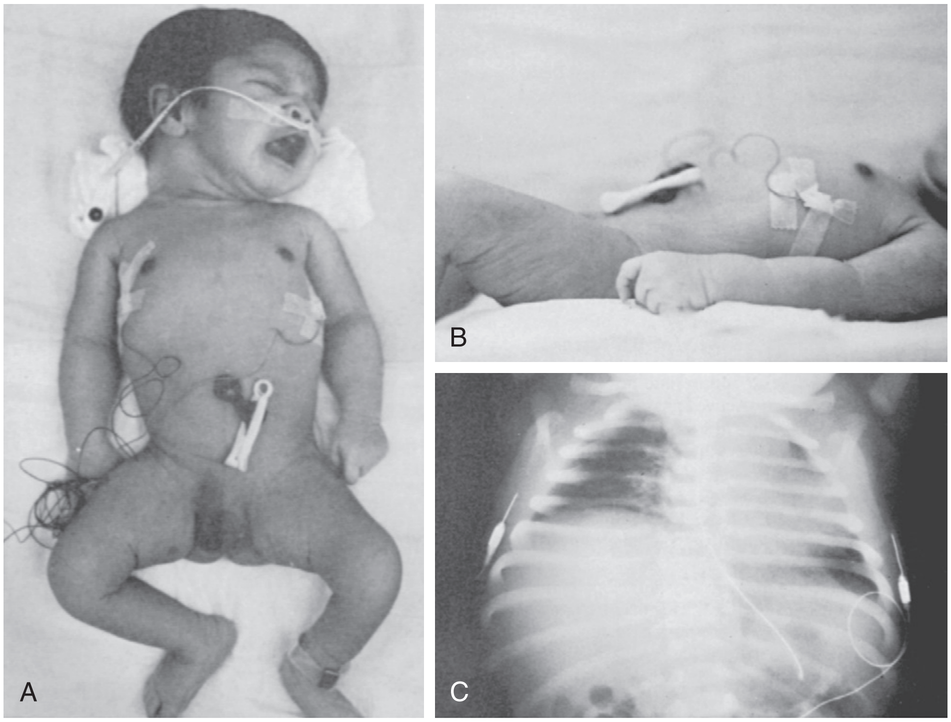

Figure 28–15. **A**, Nine-hour-old, 3190-g female infant born after difficult total breech extraction; during delivery, cervix clamped down on head, necessitating extensive tugging and pulling on both arms. Note markedly hyperexpanded chest and classic appearance of both upper extremities in Erb palsy positions. **B**, Lateral view of same infant, demonstrating increased anteroposterior diameter of chest and close-up view of left upper extremity adducted at shoulder, extended at elbow, and pronated and flexed at wrist. **C**, Significant elevation of right hemidiaphragm to level of fifth thoracic vertebra in same infant, compatible with paralysis of right hemidiaphragm. Note significant shifting of heart and mediastinum to the left.

not recovered diaphragmatic function after 30 days of conservative treatment did not demonstrate spontaneous recovery thereafter. Accordingly, these investigators recommend limiting conservative treatment to 1 month, assuming the infant is adequately oxygenated with conventional techniques. The absence of definite improvement after 1 month is considered evidence of disruption of the phrenic nerve, thereby minimizing chances of complete spontaneous recovery. Infants in this category should be considered candidates for plication of the diaphragm early in the second month of life.

PROGNOSIS

Many infants recover spontaneously. If avulsion of the cervical nerves has occurred, spontaneous recovery is not possible, and in the absence of surgery, the infant is susceptible to pneumonia in the atelectatic lung. Infants treated surgically do well, with no recurrence of pneumonia and no late pulmonary or chest wall complications.

Injury to the Sternocleidomastoid Muscle

Injury to the sternocleidomastoid muscle is designated muscular torticollis, congenital torticollis, or sternocleidomastoid fibroma. Its cause and pathologic features have been controversial.

ETIOLOGY

The birth trauma theory suggests that the muscle or fascial sheath is ruptured during a breech or difficult delivery involving hyperextension of the muscle. A hematoma develops and is subsequently invaded by fibrin and fibroblasts with progressive formation of scar tissue and shortening of the muscle. The intrauterine theory postulates abnormal pressure, position, or trauma to the muscle during intrauterine life. Another theory suggests a hereditary defect in the development of the muscle. Others have noted pathologic findings resembling infectious myositis, suggesting an infection in utero or a muscle injured at delivery. Davids and coworkers,[20] based on use of MRI to visualize live infants and cadaver dissections and injection studies, suggest that congenital muscular torticollis results from intrauterine or perinatal compartment syndrome. According to this investigation, the sternocleidomastoid muscle compartment, defined by the external investing fascia of the neck, contains only the sternocleidomastoid muscle.

In utero or intrapartum positioning of the head and neck in forward flexion, lateral bending, and rotation can result in the ipsilateral sternocleidomastoid muscle kinking on itself. If the kinking continues for a prolonged period in utero, an ischemic injury at the site could develop, followed by subsequent edema and development of a compartment syndrome. Therefore, the mechanism of injury is localized kinking or crush, in contrast to the previously suspected mechanism of stretching or tearing (Fig. 28-16).

CLINICAL MANIFESTATIONS

A mass in the midportion of the sternocleidomastoid muscle may be evident at birth, although usually it is first noted 10 to 14 days after birth. It is 1 to 2 cm in diameter, hard, immobile, fusiform, and well circumscribed; there is no inflammation or overlying discoloration. The mass enlarges during the following 2 to 4 weeks and then gradually regresses and disappears by age 5 to 8 months.

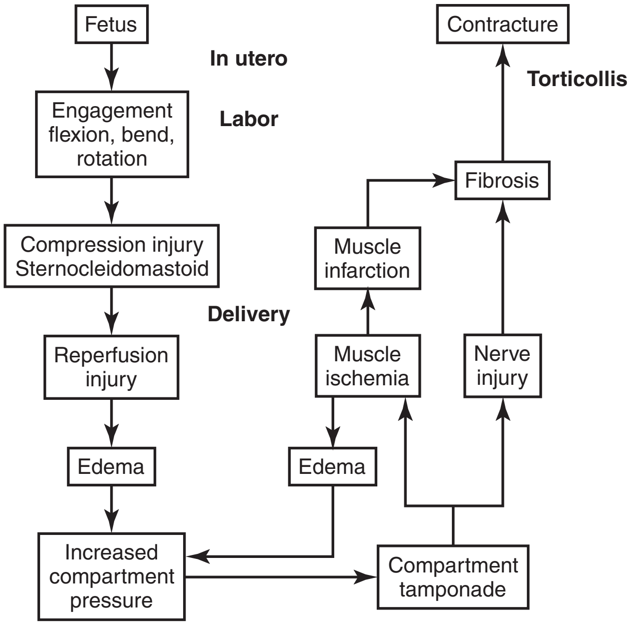

Figure 28–16. Algorithm illustrating the Davids study,[20] suggesting that congenital muscular torticollis results from intrauterine or perinatal compartment syndrome.

A transient torticollis produced by contracture of the involved muscle appears soon after birth. The head tilts toward the involved side, and the chin is somewhat elevated and rotated toward the opposite shoulder. The head cannot be moved passively into normal position. If the deformity persists beyond 3 or 4 years, the skull becomes foreshortened. Flattening of the frontal bone and bulging of the occipital bone occur on the involved side, whereas the contralateral frontal bone bulges and the occiput is flattened. The ipsilateral eyebrow is slanted; the clavicle and shoulder become elevated compared with the opposite normal side, and the ipsilateral mastoid process becomes more prominent. If treatment is not instituted, a lower cervical, upper thoracic scoliosis subsequently develops. Rarely, calcification develops in the affected muscles.

DIFFERENTIAL DIAGNOSIS

Careful radiographic examination should be made of the cervical spine and shoulders to rule out Sprengel deformity or Klippel-Feil syndrome, cervical myelodysplasia, and occipitalization of the atlas. In clinically equivocal cases, CT scans may differentiate classic muscular torticollis from other cervical soft tissue lesions that may cause torticollis (e.g., hemangioma, lymphangioma, and teratoma).

TREATMENT

Treatment should be instituted as early as possible. The involved muscle should be stretched to an overcorrected position by gentle, even, and persistent motion with the infant supine. The head is flexed forward and away from the affected side, and the chin is rotated toward the affected side.

The mother can be instructed to repeat this maneuver several times a day. The infant also should be stimulated to turn the head spontaneously toward the affected side; the crib may be positioned so that the infant must turn to the desired position of overcorrection in looking for window light or at a mobile or favorite rattle. During sleep, the infant should be placed on the side of the torticollis; in this position, sandbags should be placed on each side of the infant's body for fixation. An alternative approach involves a helmet that is custom-made for the infant. Rubber straps made of surgical drain tubing attached to the helmet are in turn fixed to the side rails of the crib at night, with appropriate adjustments made to force the infant to sleep on the prominent side of the head. This results in stretching of the shortened sternocleidomastoid muscle.

Conservative therapy should be continued for 6 months. If the deformity has not been fully corrected, surgery should be considered to prevent permanent skull and cervical spine deformities. Ultrasonography may be useful in defining the quantity of normal muscle remnant surrounding the lesion, thereby helping to determine whether the infant requires no treatment at all, conservative stretching, or surgery.[15]

Procedures that have been used include distal tenotomy, muscle lengthening, and excision of the affected muscle. All are followed by some problems. After tenotomy, contractures may recur. Lengthening is difficult because of imprecision in estimating how much elongation will be adequate for subsequent growth. Complete excision deforms the outline of the neck. Akazawa and associates[2] reported favorable results after partial resection. This was followed postoperatively with massive cotton bandaging of the neck in the neutral position for 3 weeks. Plaster casts, a brace, and physical therapy were not used. They recommend the period between 1 and 5 years of age as the optimum for surgery.

PROGNOSIS

Most infants treated conservatively show complete recovery within 2 to 3 months. If surgery is necessary and if it is performed early, the facial asymmetry will disappear almost entirely. Infants treated before their first birthday have a better outcome than those treated later, regardless of the type of treatment. Nonsurgical treatment after 1 year is rarely successful.

INJURIES TO THE SPINE AND SPINAL CORD

Birth injuries to the vertebral spine and spinal cord are rarely diagnosed. It is not certain whether the low incidence is real, reflecting improved obstetric techniques, or represents a tendency for postmortem examination to overlook spine and spinal cord lesions.

Etiology

These injuries almost always result from breech deliveries, especially difficult ones in which version and extraction were used. Other predisposing factors include brow and face presentations, dystocia (especially shoulder), prematurity, primiparity, and precipitous delivery. The injuries are usually caused by stretching of the cord. However, Hankins[37] reported an infant with lower thoracic spinal cord injury after application of maternal fundal pressure to relieve shoulder dystocia. MRI revealed focal spinal cord swelling involving T9 through T12, thought to represent ischemia or infarction due to a compressive injury. The most common mechanism responsible is probably forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis. When combined with flexion and torsion of the vertebral axis, this becomes a more significant problem. Occasionally, a snap is felt by the obstetrician while traction is exerted. Although cesarean delivery has been recommended as optimal for infants in breech presentation with a hyperextended head, Maekawa and colleagues[52] documented spinal cord injury after cesarean section. In fact, the mother had reported weak fetal movements during the third trimester, which suggests that injury was occurring before delivery. Difficulty in delivery of the shoulders in cephalic presentations may result in a similar mechanism of injury. The spinal cord is very delicate and inelastic. Its attachments are the cauda equina below and the roots of the brachial plexus and medulla above. Because the ligaments are elastic and the muscles delicate, the infant's vertebral column may be stretched easily. In addition, the dura is more elastic in the infant than in the adult. Consequently, strong longitudinal traction may be expected to cause elongation of the spinal column and to stretch the spinal cord and its membranes. The possible result is vertebral fracture or dislocation or both and cord transection. Most often, hemorrhage and edema produce a physiologic transection. The lower cervical and upper thoracic regions are most often involved, but occasionally the entire length of the spinal canal contains a heavy accumulation of blood.

Clinical Manifestations

Affected infants may follow one of four clinical patterns. Those in the first group are either stillborn or in poor condition from birth, with respiratory depression, shock, and hypothermia. They deteriorate rapidly; death occurs within several hours, often before neurologic signs are obvious. These infants usually have a high cervical or brainstem lesion.

The second group consists of infants who at birth may appear normal or show signs similar to those of the first group; these infants die after several days. Cardiac function is usually relatively strong. Within hours or days, the central type of respiratory depression that is initially present may be complicated by respiratory distress of pulmonary origin, usually pneumonia. The spinal lesion, usually in the upper or midcervical region, frequently is not recognized for several days, when flaccidity and immobility of the legs are noted. Occasionally, urinary retention may be the first symptom. Paralysis of the abdominal wall is manifested by a relaxation of the abdominal wall and bulging at the flanks when the infant is held upright. The intercostal muscles may be affected if the lesion is high enough. Sensation is absent over the lower half of the body. Deep tendon reflexes and spontaneous reflex movements are absent. The infant is constipated. The brachial plexus is involved in about 20% of all cases. The spinal column is usually clinically and radiographically normal.

The third group, with lesions at the seventh cervical to first thoracic vertebra or lower, comprises infants who survive for long periods, some for years. Paraplegia noted at birth may be transient. The lesion in the cord may be mild and reversible, or it may result in permanent neurologic sequelae with no return of function in the lower cord segments. The skin over the involved part of the body is dry and scaly, predisposing the infant to decubitus ulcers. Muscle atrophy, severe contractures, and bony deformities follow. Bladder distention and constant dribbling persist, and recurring urinary tract infections and pneumonia are common. Within several weeks or months, this clinical picture is replaced by a stage of reflex activity, or paraplegia-in-flexion. This is characterized by return of tone and rigid flexion of the involved extremities, improvement in skin condition with healing of decubitus ulcers, and periodic mass reflex responses consisting of tonic spasms of the extremities, spontaneous micturition, and profuse sweating over the involved part of the body.

Infants in the fourth group have subtle neurologic signs of spasticity thought to represent cerebral palsy. These patients have experienced partial spinal cord injuries and occasional cerebrovascular accidents.

Differential Diagnosis

During the first few weeks of life, injuries to the spinal cord may be confused with amyotonia congenita or myelodysplasia associated with spina bifida occulta[73] (see also Chapter 40). The former may be differentiated by the generalized distribution of the weakness and hypotonia and by the presence of normal sensation and sphincter control. The latter is usually associated with some cutaneous lesions over the sacral region such as dimples, angiomas, or abnormal tufts of hair; it is always associated with defects in the spinal lamina. Other conditions less often considered include transverse myelitis and spinal cord tumors, particularly in infants who demonstrate paralysis after an apparently normal labor and delivery. Cerebral hypotonia should be considered in infants who also demonstrate cranial nerve abnormalities, persistent primitive reflexes, and a dull facial appearance, contrasting to the bright, alert facies of the infant with spinal cord trauma. However, the concomitant occurrence of cerebral damage in an infant with spinal cord injury may confound the diagnosis. A final consideration is the infant with bilateral brachial plexus palsy with associated motor and sensory loss, or Horner syndrome; the demonstration of normal lower extremity function should rule out spinal cord injury.

Although somatosensory evoked potential recording has been used in establishing a diagnosis of spinal cord injury,[8] cervical responses are usually small and can be difficult to detect even in clinically normal infants; in addition, scalp potentials overlying the somatosensory cortex may be absent in normal term neonates.[47] Ultrasonography has been used to evaluate severe spinal cord injury in neonates.[6] The procedure is easily performed at the bedside with no disturbance of the patient. Initial cord edema, hematomyelia, and hemorrhage outside the cord can be assessed. MRI is the only procedure that provides a direct image of the spinal cord and clearly is the most reliable modality available to evaluate presumptive cervical spinal cord injury in the infant.[47,58] Previous limitations of ferromagnetic ventilators and monitors can now be circumvented by manual ventilation combined with nonferromagnetic monitors. Another option is the use of a nonferromagnetic ventilator.

Treatment

Treatment is supportive and usually unsatisfactory. The infant affected at birth requires basic resuscitative and supportive measures. Infants who survive present a therapeutic challenge that can be met only by the combined and interested efforts of the pediatrician, neurologist, neurosurgeon, urologist, psychiatrist, orthopedist, nurse, physical therapist, and occupational therapist.

While the infant is reasonably stable, cervical and thoracic spine radiographs should be obtained. In the rare occurrence of vertebral fracture or dislocation or both, immediate neurosurgical consultation is necessary for reduction of the deformity and relief of cord compression, followed by appropriate immobilization. Lumbar puncture in the acute period is of little practical value and may aggravate existing cord damage if the infant is excessively manipulated during the procedure. After several days, however, a persistent spinal fluid block may be demonstrated and may be an indication for exploratory laminectomy at the site of trauma. This possibility should be suspected in an infant with partial paraplegia and negative radiographs.

Prompt and meticulous attention must be given to skin, bladder, and bowel care. The position of paralyzed parts should be changed every 2 hours. Areas of anesthetic skin should be washed, dried, and gently massaged daily. Lamb's wool covers are helpful in preventing pressure necrosis of skin. Benzoin tincture applications help protect the skin in pressure areas. A decubitus ulcer is treated by scrupulous cleansing and complete freedom from weight bearing and friction. An indwelling urethral catheter should be inserted within several hours after severe cord trauma at any level. In the smaller infant, a size 3 feeding tube may be used. However, in the term infant, a size 5 feeding tube can usually be inserted. Repeated instrumentation should be avoided. Cultures of urine should be obtained weekly and as clinically indicated. Antibiotic therapy should be used only in the presence of infection. After several weeks, the infant reaches the stage of paraplegia-in-flexion, and urinary retention usually is replaced by regular episodes of spontaneous voiding. The indwelling catheter may then be removed, and postvoid bladder residuals should be measured. A renal sonogram and a conventional fluoroscopically guided voiding cystourethrogram should be obtained. If there are large postvoid residuals (>10 to 15 mL) or if the renal sonogram or cystogram shows abnormality, urodynamic studies may be necessary. A high-pressure neurogenic bladder is treated with an anticholinergic agent such as oxybutynin chloride, 0.5 to 1.5 mg/kg per day in three or four divided doses, concurrently with clean intermittent bladder catheterization every 3 to 4 hours. Treatment of the low-pressure neurogenic bladder requires only clean intermittent catheterization.

The first infection should be treated with the appropriate antibiotic for 2 weeks. After the neonatal period, this should be followed by suppressive therapy. During the first 2 months of life, this may include amoxicillin, 20 mg/kg PO in one daily dose, or ampicillin, 50 mg/kg IV daily. After 2 months, any of the following options is appropriate: trimethoprim and sulfamethoxazole (Bactrim, Septra), 2 mg/kg per day in one daily dose; nitrofurantoin (Furadantin), 1.5 to 2 mg/kg in one daily dose; or cefprozil, 15 mg/kg in one daily dose. This therapy should be continued for 6 to 12 months or longer, depending on the reversibility of the lesion. Cultures of urine should be obtained at 1 week, monthly for 3 months, and then every 3 months for 1 year or until recovery.

Fecal retention also is a common problem, especially after total cord transection. Appropriate dietary balance should aid in keeping the stools soft. Early use of glycerin suppositories at regular intervals encourages automatic defecation. Digital manipulation may be necessary to relieve fecal impaction.

Finally, physical rehabilitation should be instituted early in an attempt to minimize deformity. After several years, orthopedic procedures may still be necessary to correct contractures and bony deformities.

Prognosis

The prognosis varies with the severity of the injury. Most severe injuries result in death shortly after birth. Infants with cord compression from vertebral fractures or dislocations or both may recover with reasonable return of function if prompt neurosurgical removal of the compression is performed. Infants with mild injuries or partial transections may recover with minimal sequelae. MRI evidence of hemorrhage in the cervical spinal cord portends a poor neurologic outcome.[58] If MRI reveals extensive edema in multiple spinal cord segments without concurrent hemorrhage, complete recovery is possible.[58] Infants who exhibit complete physiologic cord transection shortly after birth without vertebral fracture or dislocation have an extremely poor outlook for recovery of function. Many die in infancy of ascending urinary tract infection and sepsis. Long-term survivors have been reported to live into their third decade. They are extremely rare, and although they may have normal intelligence and learn to walk with special appliances, these children face the late complications of pain, spasms, autonomic dysfunction, bony deformities, and genitourinary, psychiatric, and school problems.

MacKinnon and colleagues[51] have published an algorithm for predicting outcome in infants with upper cervical spinal cord injury; the algorithm is based on age at first breath and rate of recovery of breathing and limb movements in the first few weeks and months of life. For infants with rapid recovery, the prognosis was clarified by age 3 weeks. Infants who demonstrated very slow or no recovery of breathing or extremity movements by 3 months of age universally had a poor outcome. Patients with intermediate rates of recovery were thought to have an uncertain long-term prognosis at 3 months of age.

INJURIES TO INTRA-ABDOMINAL ORGANS

Although birth trauma involving intra-abdominal organs is uncommon, it frequently must be considered by the physician who cares for neonates because deterioration can be fulminant in an undetected lesion, and therapy can be very effective when a lesion is diagnosed early. Intra-abdominal trauma should be suspected in any newborn with shock and abdominal distention or pallor, anemia, and irritability without evidence of external blood loss.

Rupture of the Liver

The liver is the most frequently injured abdominal organ during the birth process. The autopsy incidence of liver injury varies from 0.9% to 9.6%.[80]

ETIOLOGY

Birth trauma is the most significant factor contributing to liver injury. The condition usually occurs in large infants, infants with hepatomegaly (e.g., infants with erythroblastosis fetalis and infants of diabetic mothers), and infants who underwent breech delivery. Manual pressure on the liver during delivery of the head in a breech presentation is probably a typical mechanism of injury. Prematurity and postmaturity also are thought to predispose the infant to this injury. Other contributing factors include asphyxia and coagulation disorders. Trauma to the liver more often results in subcapsular hematoma than actual laceration of the liver.

CLINICAL MANIFESTATIONS

The infant usually appears normal the first 1 to 3 days, but rarely for as long as 7 days. Nonspecific signs related to loss of blood into the hematoma may appear early; they include poor feeding, listlessness, pallor, jaundice, tachypnea, and tachycardia. A mass may be palpable in the right upper quadrant of the abdomen. The hematocrit and hemoglobin values may be stable early in the course, but serial determinations suggest blood loss. These manifestations are followed by sudden circulatory collapse, usually coincident with rupture of the hematoma through the capsule and extravasation of blood into the peritoneal cavity. The abdomen then may be distended, rigid, and dull to percussion, occasionally with a bluish discoloration of the overlying skin, which may extend over the scrotum in male infants. Abdominal radiographs may suggest the diagnosis by revealing liver enlargement, an abnormal course of a nasogastric tube or umbilical venous catheter, or uniform opacity of the abdomen, indicating free intraperitoneal fluid. Although paracentesis can confirm whether the latter indicates free blood in the peritoneal cavity, ultrasonography offers a noninvasive method of diagnosis.[80] Fresh intrahepatic hemorrhage appears echogenic, with possible enlargement of the involved lobe; with involution of the hemorrhage, the lesion becomes more echolucent and may disappear. CT scan of the abdomen also may assist in establishing a diagnosis of subcapsular hemorrhage without rupture.

DIFFERENTIAL DIAGNOSIS

This lesion is one of several that can result in hemoperitoneum; others include trauma to the adrenal glands, kidneys, gastrointestinal tract, and spleen. Presence of a right upper quadrant mass suggests trauma to the liver, but absence of a mass does not rule it out. Abdominal radiography, ultrasonography, and intravenous pyelography may assist in pinpointing the site of trauma, but ultimately a definitive diagnosis can be made only by laparotomy.

TREATMENT

Immediate management consists of prompt transfusion with packed red blood cells, as well as recognition and correction of any coagulation disorder. This should be followed by laparotomy with evacuation of the hematoma and repair of any laceration with sutures placed over a hemostatic agent. Any fragmented, devitalized liver tissue should be removed to prevent subsequent fatal secondary hemorrhage. Occasionally, hemostasis may be difficult to achieve at surgery. Consequently, blood transfusion and the tamponade of intra-abdominal pressure might be adequate therapy in some infants.

PROGNOSIS

In unrecognized liver trauma with formation of a subcapsular hematoma, shock and death may result if the hematoma ruptures through the capsule, reducing the pressure tamponade and resulting in new bleeding from the liver. Recognition of the possibility of liver rupture in infants with a predisposing birth history, followed by early diagnosis and prompt therapy, should improve the prognosis. Early diagnosis and correction of any existing coagulation disorder also improve the prognosis.

Rupture of the Spleen

Rupture of the spleen in the newborn occurs much less often than rupture of the liver. However, recognition of this condition is equally important because of its similar potential for fulminant shock and death if the diagnosis is delayed.

ETIOLOGY

The condition is most common in large infants, infants delivered in breech position, and infants with erythroblastosis fetalis or congenital syphilis in whom the spleen is enlarged and more friable and thereby susceptible to rupture either spontaneously or after minor trauma. An underlying clotting defect also has been implicated. Rupture of the spleen has occurred in normal-sized infants with uneventful deliveries and no underlying disease.[40]

CLINICAL MANIFESTIONS

Clinical signs indicating blood loss and hemoperitoneum are similar to those described for hepatic rupture. The hemoglobin and hematocrit values decrease, and abdominal paracentesis may reveal free blood. Several infants have been described in whom the blood was circumscribed within the leaves of the phrenicosplenic ligament and therefore was not clinically detectable. Occasionally, a left upper quadrant mass may be palpable, and radiographs of the abdomen may show medial displacement of the gastric air bubble.

DIFFERENTIAL DIAGNOSIS

Rupture of the liver and trauma to the adrenal glands, kidneys, and gastrointestinal tract must be distinguished.

TREATMENT

Packed red blood cells should be transfused promptly, and any coexisting clotting defect should be corrected. This should be followed by immediate exploratory laparotomy. Every attempt should be made to repair and preserve the spleen to prevent the subsequent increased risk for infection.[78] Packing of the wound surface with Gel-Foam and Surgicel has been used to stop the oozing of blood.[40] The Gel-Foam and Surgicel may be removed at a follow-up laparotomy within several days, at which time the spleen may be inspected for rebleeding.

PROGNOSIS

With early recognition and emergency surgery, the survival rate should approach 100%.

Adrenal Hemorrhage

Neonatal adrenal hemorrhage is more common than previously suspected; some autopsy studies have revealed a high incidence of subclinical hemorrhage. Massive hemorrhage is much less common, and the incidence is difficult to determine because the diagnosis is often unsuspected and considered retrospectively only years later, when calcified adrenal glands are unexpectedly found on radiographs or at autopsy.

ETIOLOGY

The most likely cause is birth trauma; risk factors include macrosomia, diabetes in the mother, breech presentation, congenital syphilis, and dystocia. Placental hemorrhage, anoxia, hemorrhagic disease of the newborn, prematurity, and, more recently, neuroblastoma have been implicated. Pathologic findings vary from unilateral minute areas of bleeding to massive bilateral hemorrhage. The increased size and vascularity of the adrenal gland at birth may predispose it to hemorrhage.

CLINICAL MANIFESTATIONS

Signs vary with the degree and extent of hemorrhage. The classic findings are fever, tachypnea out of proportion to the degree of fever, yellowish pallor, cyanosis of the lips and fingertips, a mass in either flank with overlying skin discoloration, and purpura. Findings suggesting adrenal insufficiency include poor feeding, vomiting, diarrhea, obstipation, dehydration, abdominal distention, irritability, hypoglycemia, uremia, rash, listlessness, coma, convulsions, and shock.

RADIOGRAPHIC MANIFESTATIONS

Initial radiographic manifestations may be limited to widening of the retroperitoneal space with forward displacement of the stomach and duodenum or downward displacement of the intestines or kidneys. In time, calcification may appear. Typically, this is rimlike and has been observed as early as the 12th day of life. After several weeks, the calcification becomes denser and retracted and assumes the configuration of the adrenal gland (Fig. 28-17). Ultrasonographic examination of the neonate is an excellent adjunctive method of diagnosis. Abdominal ultrasonography performed during the first several days may reveal a solid lesion in the location of the adrenal hemorrhage; this is thought to represent either clot fragmentation or diffuse clotted blood throughout the adrenal gland. If adrenal hemorrhage is suspected, ultrasonographic examination should be repeated at 3- to 5-day intervals. If adrenal hemorrhage has occurred, the lesion will change from a solid to a cystic appearance, coincident with liquefaction, degeneration, and lysis of the clot (Fig. 28-18).

DIFFERENTIAL DIAGNOSIS

Adrenal hemorrhage must be distinguished from other causes of abdominal hemorrhage. In addition, when a mass is palpable, the differential diagnosis must include the multiple

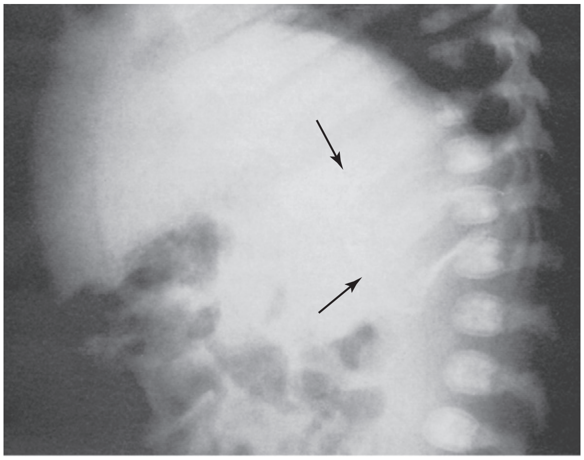

Figure 28–17. Lateral abdominal radiographs of a 5312-g male infant delivered vaginally, with difficulty after shoulder dystocia. At 48 hours, fever, icterus, and slow feeding were noted, and a mass was palpable above the left kidney. At 31 days, there was dense, retracted calcification (*arrows*) that assumed the configuration of the adrenal gland.

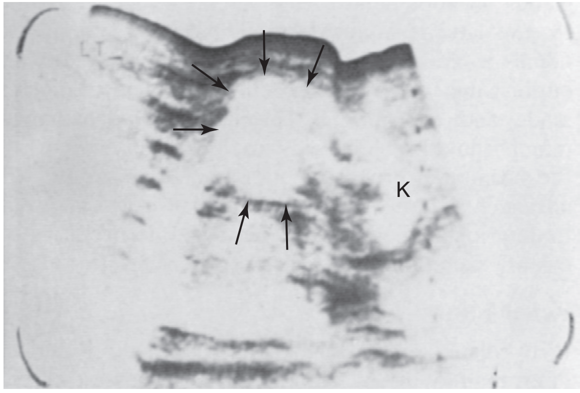

Figure 28–18. Sagittal gray-scale abdominal ultrasonographic examination of a 4564-g male infant whose mother had gestational diabetes. Problems included fracture of right clavicle, hyperbilirubinemia requiring three exchange transfusions, and abdominal distention with large left flank mass. Ultrasonographic examination at 14 days demonstrated fluid-filled mass (*arrows*) superior to left kidney (K), representing adrenal hemorrhage. *(Courtesy of Dr. John C. McFadden, Lutheran General Children's Hospital, Park Ridge, Ill.)*

causes of flank masses in the newborn, such as genitourinary anomaly, Wilms tumor, and neuroblastoma. If the infant is large or the delivery is traumatic or breech, an adrenal hemorrhage is most likely. Neuroblastoma may be distinguished by persistent demonstration of a solid lesion on serial ultrasonographic examinations and by increased excretion of vanillylmandelic acid and other urinary catecholamines in 85% to 90% of affected infants. Blood pressure measurements and radiographs also may help to evaluate this possibility.

TREATMENT

Significant blood loss should be replaced with packed red blood cell transfusion. Suspicion of adrenal insufficiency may warrant the use of intravenous fluids and corticosteroids. The decision for surgical intervention is dictated by the location and degree of hemorrhage. If it appears to be retroperitoneal and limited by the perinephric fascia, some recommend blood replacement and careful observation in the hope of spontaneous control by tamponade; often this approach is successful, and surgery is not necessary. If paracentesis reveals blood or if blood loss exceeds replacement, exploratory laparotomy is indicated. Surgery may involve evacuation of hematoma, vessel ligation, and adrenalectomy with or without nephrectomy. When the hemorrhagic process extends to the peritoneal cavity, peritoneal exploration and evacuation of clots are indicated.

PROGNOSIS

Small hemorrhages are probably often asymptomatic and have no associated significant morbidity, judging from the unexpected discovery of calcified adrenal glands on abdominal radiographs taken for other reasons later in infancy and childhood. If hemoperitoneum or adrenal insufficiency or both develop, the outlook depends on the speed with which diagnosis is made and appropriate therapy instituted. Surviving infants should be followed closely after discharge from the hospital. Adrenal function should be tested with adrenocorticotropic hormone stimulation at a later date to determine whether a normal response occurs in the urinary excretion of 17-hydroxycorticosterone.

Renal Injury

Birth-related injury to the kidneys occurs rarely and less often than injury involving the liver, spleen, or adrenal gland.

ETIOLOGY

Factors that predispose an infant to any form of intra-abdominal injury also may affect the kidneys. They include macrosomia, malpresentation (especially breech), and precipitous labor or delivery or both. The potential for renal injury is enhanced by a preexisting anomaly (e.g., hydronephrosis).

CLINICAL MANIFESTATIONS

The infant may demonstrate the same signs of blood loss and hemoperitoneum noted in the other intra-abdominal lesions. More specific signs include ascites, flank mass, and gross hematuria. Radiographs may confirm the presence of ascites and flank mass. Ultrasonographic examination may further define the mass (e.g., presence of cysts) and reveal ascites and retroperitoneal hematoma. Application of a Doppler probe to the renal hilus and the region of the vessels can assist in assessing renal arterial and venous flow. In ambiguous cases, CT scanning may help to clarify ultrasonographic findings.

DIFFERENTIAL DIAGNOSIS

Other lesions that cause hematuria must be considered. They include renal tumor with hemorrhage and renal vein thrombosis with infarction.

TREATMENT

After providing supportive measures similar to those used in other intra-abdominal injuries, the clinician should consider laparotomy. Possible findings at surgery include kidney rupture or transection, renal pedicle avulsion, and kidney necrosis. Use of an intraoperative Doppler probe can determine the status of renal blood flow. If there is no flow, nephrectomy is indicated.

PROGNOSIS

Early recognition of possible renal vascular injury may lead to earlier intervention, with the potential for kidney salvage.

INJURIES TO THE EXTREMITIES

Fracture of the Humerus

After the clavicle, the humerus is the bone most often fractured during the birth process.

ETIOLOGY

The most common mechanisms responsible are difficult delivery of extended arms in breech presentations and of the shoulders in vertex presentations. Besides traction with simultaneous rotation of the arm, direct pressure on the humerus also is a factor. This may account for the occurrence of fracture of the humerus in spontaneous vertex deliveries. The fractures are usually in the diaphysis. They are often greenstick fractures, although complete fracture with overriding of the fragments occasionally occurs.

CLINICAL MANIFESTATIONS

A greenstick fracture may be overlooked until a callus is noted. A complete fracture with marked displacement of fragments presents an obvious deformity that calls attention to the injury. Often the initial manifestation of the fracture is immobility of the affected arm. Palpation reveals tenderness, crepitation, and hypermobility of the fragments. The ipsilateral Moro response is absent. Radiographs confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes all the previously noted lesions that cause immobility of the arm. An associated brachial plexus injury occasionally occurs.

TREATMENT

The affected arm should be immobilized in adduction for 2 to 4 weeks. This may be accomplished by maintaining the arm in a hand-on-hip position with a triangular splint and a Velpeau bandage, by strapping the arm to the chest, or by application of a cast.

PROGNOSIS

The prognosis is excellent. Healing is associated with marked formation of callus. Moderate overriding and angulation disappear with time because of the excellent remodeling power of infants. Complete union of the fracture fragments usually occurs by 3 weeks. Fair alignment and shortening of less than 1 inch indicate satisfactory closed reduction. Fractures of the long bones in infants always result in epiphyseal stimulation; the closer the fracture to the epiphyseal cartilage, the greater is the degree of subsequent overgrowth.

Fracture of the Radius

Radius fracture is an extremely rare occurrence, reported in a macrosomic infant born after a shoulder dystocia.[85] There was a concurrent midhumeral shaft fracture of the other arm, with lateral displacement of the distal fragment.

ETIOLOGY

This injury, because it was a spiral fracture, was thought to have resulted from rotational maneuvers attempted to alleviate the shoulder dystocia. An alternative explanation is compressive forces related to the shoulder dystocia itself; that is, the affected arm could have incurred an extreme degree of direct compression by the overlying symphysis pubis.

CLINICAL MANIFESTATIONS

Physical findings were limited to bruising of the affected forearm. However, as in any long bone fracture, if complete with displacement of fragments, additional findings may include swelling, deformity, tenderness, and crepitation.

TREATMENT

Because of the presence of bilateral fractures, casts were placed on both arms. If it occurs as an isolated injury, without displacement, a radial fracture can be treated with simple immobilization.

PROGNOSIS

Radiographs at 2 weeks of age revealed a healed radial fracture and marked callus formation around the humeral fracture.

Fracture of the Femur

Although a relatively infrequent injury, fracture of the femur is by far the most common fracture of the lower extremity in the newborn.

ETIOLOGY

Fracture of the femur usually follows a breech delivery when the leg is pulled down after the breech is already partially fixed in the pelvic inlet or when the infant is improperly held by one thigh during delivery of the shoulders and arms. Femoral fracture even may occur during cesarean delivery.[3] Infants with congenital hypotonia may be more prone to this injury if their underlying disorder (e.g., severe Werdnig-Hoffmann disease) is associated with decreased muscle bulk at birth. Senanayake and associates[79] reported on an infant who sustained a midtrimester fracture of the femur. No apparent maternal trauma was identified during the pregnancy. The infant was otherwise normal, with no other fractures and no evidence of skeletal dysplasia. Follow-up through age 6 years revealed normal growth, with no additional fractures. The authors were unable to identify an etiology, other than possible “unnoticed maternal trauma.” It is critical to document such an occurrence to preclude inappropriate focus on the delivery process as a cause of the fracture. In addition, failure to identify and document the timing of the fracture may lead to subsequent suspicion of child abuse.

CLINICAL MANIFESTATIONS

Usually an obvious deformity of the thigh is seen (Fig. 28-19); as a rule, the bone breaks transversely in the upper half or third, where it is relatively thin. Less often, the injury may not be appreciated until several days after delivery, when swelling of the thigh is noted; this swelling may be caused by hemorrhage into adjacent muscle. The infant refuses to move the affected leg or cries in pain during passive movement or with palpation over the fracture site. Radiographs almost always show overriding of the fracture fragments.

TREATMENT

Optimal treatment is traction-suspension of both lower extremities, even if the fracture is unilateral. The legs are immobilized in a spica cast; with Bryant traction, the infant is suspended by the legs from an overhead frame, with the buttocks and lower back just raised off the mattress. The legs are extended and the thighs flexed on the abdomen. The weight of the infant's body is enough to overcome the pull of the thigh muscles and thereby reduce the deformity. The infant is maintained in this position for 3 to 4 weeks until adequate callus has formed and new bone growth has started. During the treatment period, special attention should be given to careful feeding of the infant and to protection of bandages and casts from soiling with urine and feces.

PROGNOSIS

The prognosis is excellent; complete union and restoration without shortening are expected. Extensive calcification may develop in the areas of surrounding hemorrhage but is resorbed subsequently.

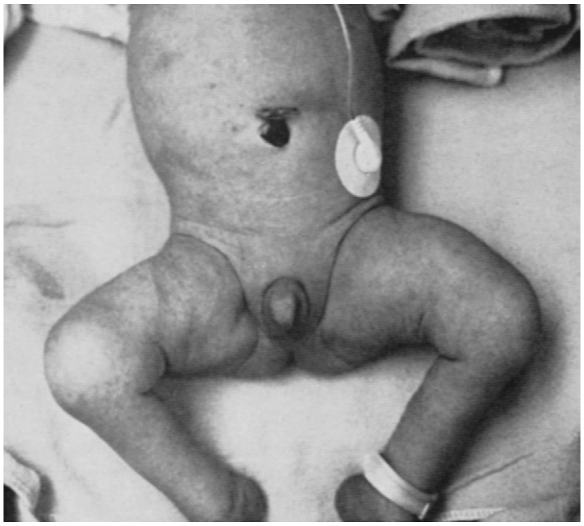

Figure 28–19. Fullness and obvious deformity of left thigh in 4020-g male infant with Werdnig-Hoffmann disease. Muscle wasting of both lower extremities also is apparent. Radiograph confirmed fracture of proximal third of left femur.

Dislocations

Dislocations caused by birth trauma are rare. Often an apparent dislocation is actually a fracture displaced through an epiphyseal plate. Because the epiphyseal plate is radiolucent, a fracture occurring adjacent to an unmineralized epiphysis gives a radiographic picture simulating a dislocation of the neighboring joint. This type of injury has been termed *pseudodislocation*.[36] Because the humeral and proximal femoral epiphyses are usually not visible on radiographs at birth, a pseudodislocation can occur at the shoulder, elbow, or hip.

Of the true dislocations, those involving the hip and knee are probably not caused by the trauma of the birth process. Most likely they are either intrauterine positional deformities or true congenital malformations. A true dislocation resulting from birth trauma is that involving the radial head. This has been associated with traumatic breech delivery. Examination reveals adduction and internal rotation of the affected arm, with pronation of the forearm; Moro response is poor, and palpation reveals lateral and posterior displacement of the radial head. This is confirmed by radiographs. With supination and extension, the radial head can be reduced readily. This should be done promptly, followed by immobilization of the arm in this position in a circular cast for 2 to 3 weeks. Early recognition and treatment should result in normal growth and function of the elbow.

Bayne and associates[7] illustrated the importance of establishing an early diagnosis when they described a term infant with a swollen, tender elbow after breech delivery. Movement produced obvious pain. Radiographs at that time and again at 8 months of age were misinterpreted as normal. At 1 year, an orthopedist diagnosed anteromedial dislocation. Because of several unsuccessful attempts at closed reduction, future osteotomy was required to treat this now permanent deformity.

Epiphyseal Separations

As with dislocations, epiphyseal separations are rare. They occur mostly in primiparity, dystocic deliveries, and breech presentations, especially those requiring manual extraction or version and extraction. Any delivery associated with vigorous pulling may predispose the infant to this injury. The upper femoral and humeral epiphyses are most often involved. Usually on the second day, the soft tissue over the affected epiphysis develops a firm swelling with reddening, crepitus, and tenderness. Active motion is limited, and passive motion is painful. If the injury is in the upper femoral epiphysis, the infant assumes the frog-leg position with external rotation of the leg.

Early radiographs show only soft tissue swelling, with occasional superolateral displacement of the proximal femoral metaphysis. Because the neonatal femoral capital epiphysis is not ossified, this can be mistakenly interpreted as congenital hip dislocation. However, the presence of pain and tenderness would make dislocation unlikely. Besides plain radiographs of the hips, an infant with a history and physical examination compatible with traumatic epiphysiolysis should also undergo ultrasonography before manipulation is attempted. This examination would demonstrate a normal femoroacetabular relationship, in contrast to the abnormal findings in an infant with septic arthritis and congenital hip dislocation. In addition, in the presence of traumatic epiphysiolysis the femoral head and neck would not be continuous, in contrast to the findings of septic arthritis and congenital hip dislocation. Further differentiation between traumatic epiphysiolysis and septic arthritis can be provided by arthrocentesis; in epiphysiolysis, the joint does not contain excess fluid, and what is obtained may be serosanguineous, whereas in septic arthritis, purulent fluid is obtained. After 1 to 2 weeks, extensive callus appears, confirming the nature of the injury; during the third week, subperiosteal calcification appears.

If possible, treatment should be conservative. Closed reduction and immobilization are indicated within the first few days before rapidly forming fibrous callus prevents mobilization of the epiphysis. The hip is immobilized in the frog-leg position, as in congenital dislocation. Poorly immobilized fragments of the proximal or distal femur (Fig. 28-20) may require temporary fixation with a Kirschner wire (Fig. 28-21).[54] Union usually occurs within 10 to 15 days. Untreated or poorly treated epiphyseal injuries may result in subsequent growth distortion and permanent deformities such as coxa vara. Mild injuries carry a good prognosis.

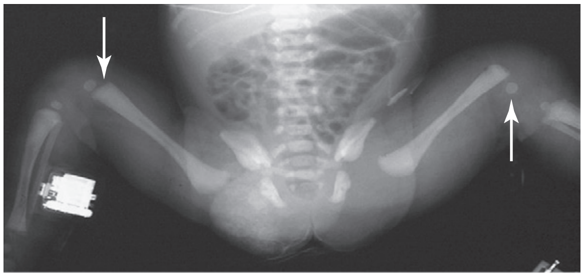

Figure 28–20. Radiograph of lower extremities of 4205-g male delivered precipitously after complete breech presentation. Radiograph demonstrates displaced distal femoral physeal fracture on left (*arrow*) and nondisplaced distal femoral physeal fracture on right (*arrow*). Deep Tendon Injuries

Accidental fetal injury is a serious but underreported complication of emergency cesarean deliveries. Although the most commonly documented injury is superficial skin laceration, deeper and more serious injuries have been described, including amputation of the distal digits and tendon injuries requiring surgical intervention.[1] A prospective study at 13 university centers in the United States revealed an incidence of fetal injury of 1.1% during emergency cesarean section, with skin lacerations accounting for 64% of injuries overall.[4] Neonatal tendon injuries during cesarean section have previously been reported only twice in the literature.[28,45] Recently, Prazad and associates[68] reported a case of severe multiple extensor tendon lacerations with open metacarpophalangeal joints (Fig. 28-22) sustained at the time of an emergency cesarean delivery.

RISK FACTORS ASSOCIATED WITH DEEP TENDON INJURY

Several factors associated with increased risk for fetal laceration and fetal injury are emergency cesarean delivery, shortened duration between abdominal skin incision and delivery of infant, type of uterine incision, premature rupture of membranes, abnormal fetal presentation, and active labor.[4,34,92]

MANAGEMENT

Even though multiple surgical techniques have been described for adults with the same kind of injury, there is no information available regarding a favorable surgical approach in neonates. Fuller and colleagues[28] described

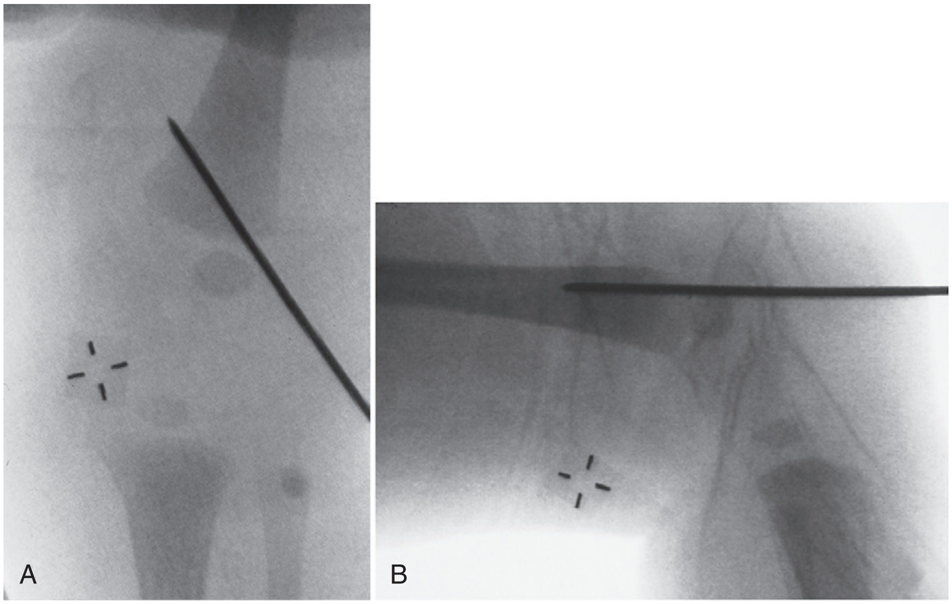

Figure 28–21. Because of unsuccessful attempts at closed reduction of left-sided fracture, a Kirschner wire was inserted to provide secure fixation of fracture fragments, anteroposterior view (**A**) and lateral view (**B**). (*From Mangurten HH, et al: Neonatal distal femoral physeal fracture requiring closed reduction and pinning,* J Perinatol *25:216, 2005.)*

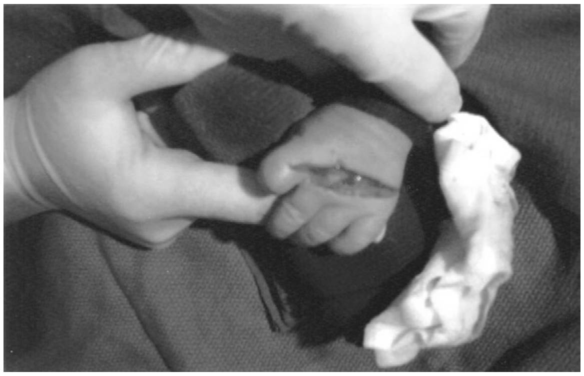

Figure 28–22. Laceration extending from index finger to baby finger, with open metacarpophalangeal joints. There were complete extensor tendon lacerations of middle, ring, and baby fingers, with partial laceration of index finger. See color insert. *(From Prazad P, et al: Complication of emergency cesarean section: open metacarpophalangeal disarticulation and complete extensor tendon lacerations of the hand in a neonate,* J Neonat Perinat Med *2:131-133, 2009.)*

two different methods of extensor tendon repair. Laceration in one finger was closed in a single layer using a full-thickness stitch through the skin and extensor mechanism, and laceration in the second finger was repaired in two layers. Excellent clinical outcome of both fingers was noted after surgery. Kavouksorian and coworkers[45] reported a flexor tendon laceration of the hand that occurred during emergency cesarean delivery with excellent functional results despite delayed primary closure. Prazad and colleagues[68] used immediate (within 3 hours of birth) microsurgical repair at the bedside under local field block anesthesia to achieve an excellent functional outcome at 18 months of age.

Other Peripheral Nerve Injuries

In contrast to the brachial plexus and phrenic and facial nerves, other peripheral nerves are injured less often at birth and usually in association with trauma to the extremity. Radial palsy has occurred after difficult forceps extractions, both from pressure of incorrectly applied forceps and in association with fracture of the arm. Occasionally, the palsy occurs later, when the radial nerve is enmeshed within the callus of the healing fracture. Frequently, associated subcutaneous fat necrosis overlies the course of the radial nerve along the lateral aspects of the upper arm. The presence of isolated wristdrop with weakness of the wrist, finger, and thumb extensors, skin changes overlying the course of the nerve, and absence of weakness above the elbow distinguish this condition from brachial plexus injury. Palsies of the femoral and sciatic nerves have occurred after breech extractions; sciatic palsy has followed extraction by the foot. Passive range-of-motion exercises are usually the only therapy required. Complete recovery usually occurs within several weeks or months.

TRAUMA TO THE GENITALIA

Soft tissue injuries involving the external genitalia sometimes occur, especially after breech deliveries and in large infants.

Scrotum and Labia Majora

Edema, ecchymoses, and hematomas can occur in the scrotum and labia majora, especially when they are the presenting parts in a breech presentation. Because the male newborn has a pendulous urethra that is vulnerable to compression or injury, it is possible for significant trauma to occur after a protracted labor in the breech position; the mechanism is believed to be compression of the urethra against a firm structure in the maternal bony pelvis. Rarely this may cause marked temporary hydronephrosis after delivery. The hydronephrosis usually resolves within 3 days. Because of laxity of the tissues, the degree of swelling and of discoloration occasionally is extreme enough (Fig. 28-23) to evoke considerable concern among the medical and nursing staff, especially regarding deeper involvement (e.g., periurethral hemorrhage and edema), which might hinder normal micturition. However, this has not generally been a problem, and frequently these infants void shortly after arriving in the nursery. Spontaneous resolution of edema occurs within 24 to 48 hours, and resolution of discoloration occurs within 4 to 5 days. Treatment is not necessary. Secondary ulceration, necrosis, or eschar formation is rare unless an associated underlying condition such as herpes simplex virus infection is present.

Marked scrotal hematoma may simulate testicular torsion, particularly when accompanied by a solid scrotal mass.[23] Because untreated torsion may result in loss of the testis, it is critical to distinguish the two lesions. This may be done by Doppler ultrasonography. If blood flow to the testes is clearly demonstrated, and if the testes appear symmetric in size and echotexture, torsion may essentially be ruled out.[23]

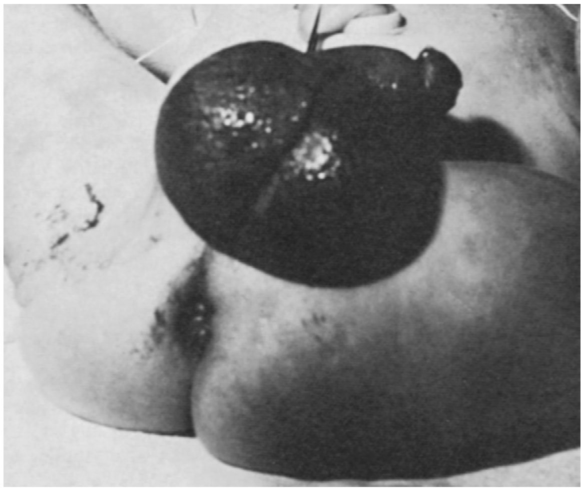

Figure 28–23. Hematoma of scrotum and penis in 3895-g male infant delivered vaginally after frank breech presentation. Infant voided at 22 hours and regularly thereafter. Swelling diminished appreciably within 5 hours and was gone by third day. Discoloration was greatly diminished by second day.

Deeper Structures

Much less often, birth trauma may involve the deeper structures of the genitalia. If the tunica vaginalis testis is injured and blood fills its cavity, a hematocele is formed. Absence of transillumination distinguishes this from a hydrocele. If it appears that the infant is in pain, the scrotum may be elevated and cold packs applied. Spontaneous resolution is the usual course.

The testes may be injured, often in association with injury to the epididymis. Usually the involvement is bilateral. The testes may be enlarged, smoothly rounded, and insensitive. The infant may be irritable, with vomiting and poor feeding. Urologic consultation is indicated; occasionally, exploration and evacuation of blood are necessary, especially with increasing size of the testes. Severe trauma may result in atrophy or failure of the testes to grow. The occasional finding in older children of a circumscribed fibrous area within the testicular tissue is thought to represent past birth trauma to the gland.

INJURIES RELATED TO INTRAPARTUM FETAL MONITORING

Continuous monitoring of the fetal heart rate and the intermittent sampling of fetal scalp blood for determination of acid-base status often are used to monitor the fetus during labor. Thousands of patients have been monitored by these methods (see also Chapters 10 and 31). The relative infrequency of complications indicates that in experienced hands, these procedures are generally safe. However, certain specific complications have occurred.

Injuries Related to Direct Fetal Heart Rate Monitoring

Direct monitoring of the fetal heart rate during labor depends on application of an electrode to the fetal scalp or other presenting part. Superficial abrasions, lacerations, and hematomas can occur rarely at the site of application of the electrode. These complications require no specific therapy beyond local treatment.

Rarely, abscesses of the scalp may follow application of scalp electrodes. These abscesses usually have been sterile and have required only local treatment. Systemic signs or symptoms require evaluation for possible septicemia.

Lauer and Rimmer[48] reported a potentially more serious complication related to use of a spiral fetal scalp electrode, as noted earlier in this chapter. At delivery, the electrode was noted to be attached to the infant's eyelid, resulting in a superficial laceration. Marked surrounding edema was considered to have protected the infant from more severe injury.

Injuries Related to Fetal Scalp Blood Sampling

Fetal biochemical monitoring requires puncture of the presenting part, usually the scalp, with a 2-mm blade and the collection of blood under direct visualization in a heparinized tube. Major complications that may occur rarely are excessive bleeding and accidental breakage of the blades. The bleeding can be stopped by pressure, but on occasion this requires sutures. Rarely blood replacement may be required. It is important to obtain a detailed family history of bleeding disorders before initiation of this procedure.

The second major complication has been breakage of the blade within the fetal scalp. Removal soon after delivery has been recommended to prevent secondary infection. This has been accomplished by use of a magnet attached to a small forceps that probes the puncture site and elicits a click as the blade is attracted to the magnet. On occasion, radiographic localization followed by a small incision is necessary for withdrawal of the blade.

INJURIES RELATED TO ACCIDENTAL AND INFLICTED TRAUMA INCURRED BY THE MOTHER

Trauma to women during pregnancy continues to be a major cause of maternal, fetal, and neonatal mortality and morbidity. Motor vehicle collisions, gunshot wounds, violent assaults, and suicides top the list. Gunshot wounds, in particular, during pregnancy may result in devastating effects on both mother and fetus throughout gestation. Not only may mother and fetus sustain significant organ damage, but also the extent of the physical maternal injury may dictate preterm delivery (Fig. 28-24). Prognosis usually is worse in the fetus than the mother. In a review of 119 cases of gunshot injuries to the uterus, Buchsbaum reported a perinatal mortality rate of 66%.[12] A well-coordinated team of surgeons, obstetricians, and neonatologists providing timely and comprehensive management may improve this outcome.

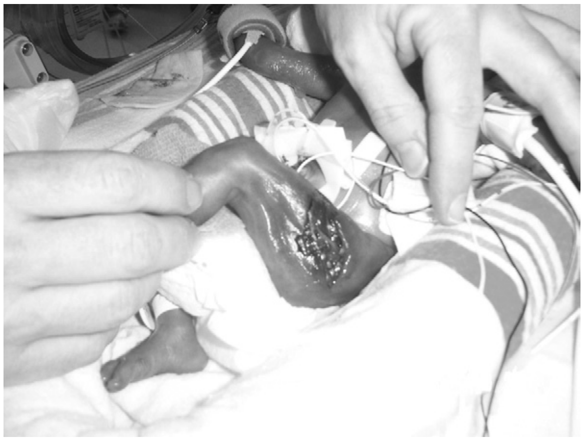

Figure 28–24. Deep skin wound lateral surface left thigh in 6-hour-old, 845-gm preterm female infant delivered by emergency cesarean birth after mother sustained a gunshot wound to the abdomen. See color insert.

CHAPTER 29

Congenital Anomalies

Aditi S. Parikh and Georgia L. Wiesner

Major anomalies are seen in about 2% of newborns, often prompting parental worry and urgent medical intervention soon after birth. In addition, they are a common cause of long-term illness and death. This chapter reviews some of the significant etiologic and epidemiologic aspects of congenital anomalies. It provides an approach to and a framework for the evaluation of the infant with congenital anomalies, with emphasis on conditions that are apparent in the delivery room. More detailed and complete differential diagnoses for each anomaly can be found in other sources.

GENERAL CLINICAL APPROACH

The neonatologist or perinatologist often is the first person to identify a congenital anomaly and initiate the necessary medical evaluations. In essence, the clinician observes an abnormal *phenotype*, which is a term used to describe the identifiable manifestation of a person's genotype, or the genetic constitution of an individual. This observation is followed by the generation of possible causes, which are confirmed or refuted with further testing. Because the underlying defect or genotype is often not known, phenotype in clinical practice refers to a collection of specific traits, physical findings, and the results of medical tests, such as laboratory, pathologic, and radiologic studies.

A *congenital anomaly* is an internal or external structural defect that is identifiable at birth. Anomalies are deviations from the norm and are classified as either a major or minor anomaly. A major anomaly is a defect that requires significant surgical or cosmetic intervention, such as tetralogy of Fallot or cleft lip and palate, whereas a minor anomaly has no significant surgical or cosmetic importance. The clinician should be aware that minor anomalies often overlap with normal phenotypic variation, so a careful search for specific morphologic patterns is essential. It is important to classify an anomaly as major, minor, or normal because their implications differ for both the infant and the family. It is also important to distinguish the concepts of *congenital* and *genetic,* terms that are often confused. Congenital merely indicates that the feature is present at birth and can be due to many genetic and nongenetic causes.

Anomalous external physical features are called *dysmorphisms* and can be clues to the underlying cause or developmental defect. A useful approach to determining the etiology of a congenital anomaly is to consider whether it represents a malformation, deformation, or disruption of normal development.[52] In a study of 27,145 neonates with congenital anomalies, nearly 98% were due to an underlying malformation, which is a primary structural defect in tissue formation, such as a neural tube defect or a congenital heart defect. A *malformation* implies an abnormal morphogenesis of the underlying tissue due to a genetic or teratogenic factor.[36] In contrast, a deformation results from abnormal mechanical forces acting on otherwise morphologically normal tissues.[1,52] Deformations primarily result from mechanical forces, such as intrauterine constraint, on the growing fetus. A variety of maternal factors can cause fetal constraint, and common examples include breech or other abnormal positioning in utero, oligohydramnios, and uterine anomalies. Clubfoot and altered head shape are frequent anomalies that can result from constraint. Deformations occurring late in gestation often are reversible with changes in position or removal of the force. Observing the position the infant finds most comfortable along with a careful obstetric history of fetal movement, position, and fluid volume can be helpful in determining whether an anomaly could have been caused by a deforming force. A disruption represents the destruction or interruption of intrinsically normal tissue, and it usually affects a body part rather than a specific organ. Vascular occlusion and amniotic bands are common causes of disruptions. Monozygotic twinning and prenatal cocaine exposure are common predisposing factors for disruptions on the basis of vascular interruption.

Malformations may predispose a fetus to additional deformations and multiple anomalies. A neural tube defect, a malformation, causes fetal deformations of hip dislocation and clubfoot, owing to lack of movement below the level of the lesion. If an infant has more than one anomaly, the clinician should then consider whether it is part of a sequence, association, or a known syndrome. Sequence refers to a pattern of multiple anomalies derived from a single known or presumed cause. An example is the oligohydramnios sequence, often referred to as *Potter syndrome*, which consists of limb deformations, pulmonary hypoplasia, and Potter facies of a beaked nose, infraorbital creases, and simple ears. These features are due to a lack of amniotic fluid during gestation, secondary to chronic leakage of amniotic fluid or lack of fetal urine (renal agenesis, a malformation).[29,52] Another constellation of anomalies frequently seen by the neonatologist is the Pierre Robin sequence, consisting of micrognathia, cleft palate, and glossoptosis, in which the disproportionately small malformed mandible causes the tongue to move backward and upward in the oral cavity during development resulting in a cleft palate.[16,29] In these instances, the key to understanding the underlying cause of the secondary deformation anomalies lies with the primary malformation.

Multiple congenital anomalies in infants can also be seen as part of an association, which refers to a nonrandom occurrence of multiple malformations for which no specific or common etiology has been identified. An example is the VATER (or VACTERL) association, an acronym for a pattern of anomalies consisting of *v*ertebral abnormalities, *a*nal atresia, (*c*ardiac anomalies), *t*racheo*e*sophageal fistula, and *r*enal and *r*adial (*l*imb) dysplasia.[30,48] Although several conditions, such as maternal diabetes, are found in conjunction with VATER, a specific genetic link has not been proved. Over time, the genetic cause for some idiopathic associations has been identified, as in the CHARGE association, now known as CHARGE syndrome. The acronym denotes multiple features of the syndrome (*c*oloboma, *h*eart anomalies, choanal *a*tresia, *re*striction of growth and development, and *g*enital and *e*ar anomalies), and mutations in the *CHD7* gene were found to be causative in at least half of affected children, although the exact mechanism for the multiple malformations is not clear at this time.[55] Further, many new genes have been identified for specific syndromes that have been recognized by dysmorphologists as mendelian traits for many years. In genetic terms, a syndrome refers to a recognized pattern of anomalies with a specific, usually heritable, cause, such as the Holt-Oram syndrome, in which radial dysplasia and cardiac defects occur as a consequence of an autosomal dominant *TBX5* gene.[2,49] The Cornelia de Lange syndrome is another example of this forward progress in genetic understanding of recognized malformation syndromes, in which at least three genetic loci, including the *NIPBL* gene, have been identified in patients with growth failure, microcephaly, limb anomalies, and characteristic facial dysmorphisms.[12] It is expected that the discovery of new genetic defects will continue at a rapid pace, improving the diagnostic capability for infants with congenital anomalies in the future.

Although the underlying causes of congenital anomalies are heterogeneous, disruptions and isolated deformations are usually sporadic, with negligible or low recurrence risks. However, congenital malformations can also have more than one cause, often with different possible associated anomalies and different recurrence risks. Cleft lip and palate, for example, can be isolated or can be part of dozens of different syndromes due to monogenic, multifactorial, or complex, chromosomal, or teratogenic causes.[21] The clinician should remember that the search for the underlying cause of a birth defect can be anxiety provoking for parents of newborns with congenital anomalies, as are the implications for future children and other family members. Evaluating the newborn for a pattern of major and minor anomalies will assist the clinician in more efficiently determining the appropriate tests and procedures for diagnosis and management of a congenital anomaly, and determining future recurrence risks for family members.

EPIDEMIOLOGY AND ETIOLOGY

Major Malformations

About 2% of newborn infants have a serious anomaly that has surgical or cosmetic importance (Table 29-1).[4] Most of these infants have a single anomaly, but this proportion is a minimum estimate because it is based only on the examination of newborn infants; additional anomalies are detected with increasing age.[37] The most common anomalies are structural heart defects, cleft lip and palate, and neural tube defects, occurring in 5 to 7 per 1000, 1.5 per 1000, and 0.3 per 1000 live births, respectively.[3,4,7,47] Identifying neonates with a major malformation is medically important because they have a fivefold increase in morbidity and, if identified in the prenatal setting, have a threefold increased risk for death in utero.[33] From a genetic perspective, the etiology of malformations can be divided into broad categories: genetic (multifactorial, single gene [mendelian], or chromosomal), environmental or teratogenic, and unknown.

GENETIC

Complex or Multifactorial

The largest number (86%) of congenital malformations are isolated and not associated with other anomalies.[27] The most common and familiar birth defects fall into this category, including congenital heart defects, neural tube defects, cleft lip and palate, clubfoot, and congenital hip dysplasia (see Table 29-1). Most isolated malformations are believed to be the consequence of multifactorial inheritance, sometimes called *complex inheritance,* occurring when one or more genetic susceptibility factors combine with environmental factors and random developmental events.[22] In most cases, multiple genetic components are involved, some with large effects and some with small contributions. From a public health standpoint, the nongenetic effects have been harder to identify in most cases, although work has begun to link specific gene sequence variants to environmental factors. For example, epidemiologic studies have demonstrated that neural tube defects are associated with many maternal factors, such as hyperthermia, glucose levels, and folate intake.

TABLE 29–1 Birth Defects Among Hospitalized Newborns, 1997-2001

Defect Category	Rate per 10,000
Central nervous system	4.51-8.34
Ear, eye	2.7-7.9
Orofacial	16.22-18.32
Cardiovascular	106.19-110.77
Gastrointestinal	6.3-6.7
Genitourinary	52.04-55.61
Musculoskeletal	10.28-14.15

Data from Bird TM, et al: National rates of birth defects among hospitalized newborns, *Birth Defects Res Part A* 76:762, 2006.

The genetic contribution may be exemplified by a recent study that showed a sequence variation in the promoter of the *PDGFRA* gene was associated with the formation of neural tube defects in the offspring of mothers with a high body mass index and glucose levels.[53]

Single Gene (Mendelian)

Single major genes are responsible for causing 0.4% of newborns to have major malformations. The most common mode of mendelian inheritance for major malformations is autosomal dominant, with a minority of major malformations resulting from autosomal recessive or, rarely, X-linked genes. Limb anomalies, including postaxial polydactyly, syndactyly, and brachydactyly, constitute the most prevalent major localized malformations, and they are frequently the result of a dominant gene. Any type of malformation, however, may be under the control of a single gene, including multiple anomalies arising in different structures or organ systems. The mechanisms of monogenic malformation disorders are related to the dysfunction of the gene or disruption of the developmental pathway. For example, autosomal recessive Smith-Lemli-Opitz syndrome, characterized by genital abnormalities, syndactyly of the second and third toes, ptosis, wide alveolar ridges, hypotonia, inverted nipples, and abnormal fat distribution, has been found to be due to a deficiency of the enzyme 7-dehydrocholesterol reductase in the cholesterol biosynthesis pathway.[28,42] Since the genetic cause of this disorder was identified, other single gene disorders of cholesterol biosynthesis have been identified that result in multiple congenital anomalies.[41] Although a biochemical or molecular basis increasingly is being recognized, specific diagnosis still relies heavily on the family history and clinical evaluation.

Chromosomal

(See also Chapter 8)

About 0.2% of newborns have a major malformation as a result of a chromosomal disorder, amounting to 10% of all the major congenital malformations (Table 29-2). It is important to note, however, that although about 0.6% of newborns have chromosomal anomalies, the abnormalities are not detectable by physical examination at birth in 66% of these infants.[26] Included among these early phenotypically undetectable chromosomal anomalies are common aneuploidies of the sex chromosomes, such as 47,XXY, 47,XYY, and 47,XXX. Neonates with these sex chromosome disorders may not have obvious malformations in the newborn period because the phenotype may develop over time. The most prevalent malformation syndrome due to an abnormal chromosomal constitution in newborns is Down syndrome, or trisomy 21, which occurs in about 1 in 660 births.[26] The other common trisomies are trisomy 18 and trisomy 13, each occurring in about 1 in 10,000 births. All three trisomies, 47,XXY and 47,XXX, occur more frequently with increased maternal age. Other well-known chromosomal syndromes are Klinefelter syndrome (47,XXY), occurring in 1 in 1000 male births, and Turner syndrome (45,X), present in 1 in 5000 female births.

Many other types of chromosomal aberrations have been identified using standard karyotype and newer genomic technologies. In addition to detecting the gain or loss of a single chromosome, routine chromosome banding techniques can identify many translocations, inversions, ring chromosomes, marker chromosomes, and deletions.[46] However, not all deletions are detectable by routine or even high-resolution (prometaphase) cytogenetic analysis, so that additional methodologies, such as fluorescence in situ hybridization (FISH) or comprehensive genomic technologies, should be considered if the initial karyotype result is normal. FISH uses fluorescently labeled DNA probes that identify deletions in specific locations on the chromosome metaphase spread, such as those associated with such conditions as Williams syndrome (long arm of chromosome 7), Prader-Willi syndrome (long arm of chromosome 15), and velocardiofacial/DiGeorge syndrome (long arm of chromosome 22).[19]

Although FISH has greatly improved the diagnostic testing for conditions involving multiple congenital anomalies, it may be quickly supplanted by testing with newer genomic technologies that simultaneously examine the entire structure of the chromosomes.[13] Clinically available comparative genomic hybridization (CGH) or chromosomal microarray analysis arrays target known microdeletion syndromes, subtelomeres, and pericentric regions and appear to be more

TABLE 29–2 Etiology of Human Congenital Malformations

Etiology	Malformed Live Births (%)

sensitive than routine karyotype analysis. In a relatively short period of time, array analysis has revolutionized the diagnosis of neonates and children with multiple anomalies or developmental delay.[13] One example is an analysis of 1176 cases evaluated by a clinical genetics laboratory in which 9.8% had pathogenic chromosomal imbalances identified by CGH array, compared with 2% using routine karyotyping.[40] Other studies have shown that infants with multiple congenital anomalies may have a higher rate of imbalances because 17% of 444 neonates with a variety of malformations had clinically significant aneuploidies found on microarray analysis.[34] Further, new microdeletion syndromes of developmental delay and multiple malformations have been identified at 1q41-q42, 16p11-p12.1, and other loci, which suggests that whole genome analysis technologies of the future will improve diagnosis and expand our knowledge of clinically significant areas of the genome.[51]

ENVIRONMENTAL EXPOSURE AND TERATOGENS

(See also Chapter 12)

A teratogen is anything external to the fetus that causes a structural or functional disability in prenatal or postnatal life. Teratogens can be drugs and chemicals, altered metabolic states in the mother, infectious agents, or mechanical forces. Known teratogenic factors cause only 5% to 10% of congenital anomalies despite the ever-expanding list of potential teratogens in our increasingly chemical environment (see Table 29-2).[5] Before one can attribute malformations to a teratogenic agent, there must be one anomaly, only a few specific anomalies, or a recognizable pattern of anomalies found to occur at increased incidence over the background risk in infants exposed at the appropriate developmental stage (usually 2 to 12 weeks' gestation). With only a few exceptions, teratogenic agents do not affect every exposed infant, which is probably related to genetic susceptibility factors. Dose and timing of exposure also alter the potential of a specific teratogenic agent. To assess for specific drug teratogenic effects, multiple resources are available.[24]

Although beyond the scope of this chapter, pharmaceutical agents and environmental toxins are well documented to alter the development of the fetus.[57] Although many drugs have teratogenic potential, the clinician should be aware of the teratogenic effect of some commonly used drugs and exposures. Alcohol is thought to be the most common teratogen to which a fetus may be exposed. Chronic maternal alcohol use during pregnancy is associated with increased perinatal mortality and intrauterine growth restriction, as well as congenital anomalies such as cardiac defects, microcephaly, short palpebral fissures, and other anomalies (Fig. 29-1). Long-term effects include mental retardation and behavioral problems. Alcohol carries serious risks when it is used almost at any time during pregnancy in sufficient quantities because the central nervous system continues to develop throughout pregnancy. For this reason, it is recommended that women avoid alcohol, even in small amounts, throughout their pregnancy (see Chapter 38, Part 2).

Anticonvulsants are a common category of teratogens to which a fetus is likely to be exposed. Although the medical literature is somewhat controversial, clinical geneticists, dysmorphologists, and clinical teratologists generally identify a variable but recognizable pattern of anomalies and developmental defects that occur at a significantly increased frequency among fetuses exposed to older classes of anticonvulsants. Recent studies have implied that newer classes of epileptic medications may not have the same effect on the developing fetus, although the clinician should be cautious in interpreting these studies.[25] Some altered metabolic states in the mother also are known to have teratogenic potential. One of the most common is maternal diabetes mellitus. Infants of diabetic mothers are at two to three times the risk for congenital heart defects, caudal regression and sacral dysgenesis, and central nervous system abnormalities.[15] In this population, there is about a threefold increase in congenital anomalies over those in the general population. The risk for congenital anomalies appears to be lower in offspring of diabetic mothers with better control of blood glucose, but this is not absolute, and factors other than blood glucose levels are thought to play a role in teratogenesis (see Chapter 16 and Chapter 49, Part 1). Another example is untreated maternal phenylketonuria (PKU), in which the elevated levels of phenylalanine cause microcephaly, growth delay, and cardiac and neurologic abnormalities in the developing fetus.

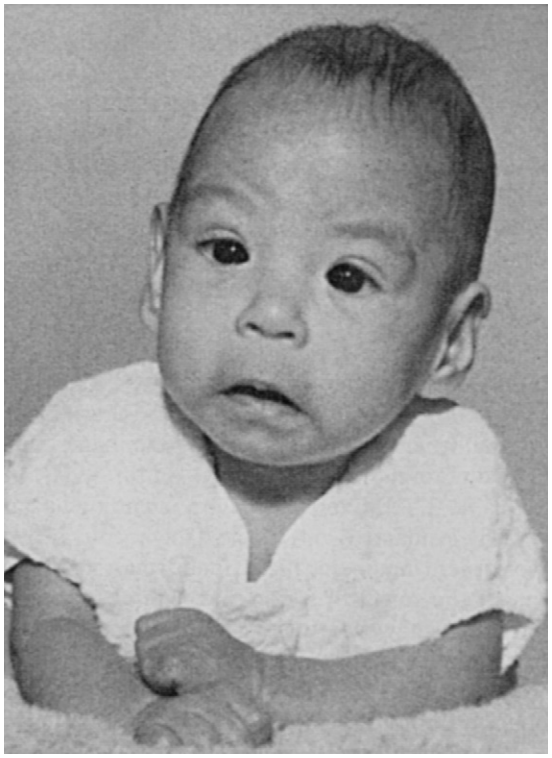

Figure 29–1. Fetal alcohol syndrome. Note mild ptosis, epicanthal folds, flat nasal bridge, short nose, smooth philtrum, and thin upper vermilion border. *(From Dworkin PH, ed.* Pediatrics, *2nd ed. Malvern, Pa, Lea & Febiger, 1992, p 168.)*

Congenital anomalies also may be associated with certain infections during pregnancy. The most common and best understood infections are represented by the acronym TORCH, which stands for *t*oxoplasmosis, *o*ther agents (including syphilis), *r*ubella, *c*ytomegalovirus, and *h*erpes simplex. Although the sequelae of these infections may not be apparent until later, the clinician should consider these congenital infections in neonates with intrauterine growth restriction, microcephaly, chorioretinitis, intracranial calcification, microphthalmia, or cataracts. Confirmation of the specific diagnosis should be made by antibody studies and other evaluations such as ophthalmologic examination and imaging studies (see Chapters 23 and 39).

UNKNOWN

About 66% of major malformations have no recognized etiology if one includes those of presumed polygenic and multifactorial etiology (see Table 29-2).[5] It is presumed that specific genetic or environmental causes of these congenital anomalies will be identified in the future as medical knowledge about the underlying biology of embryonic development and the technology for identifying gene-environment interaction improves. For example, folic acid has been recognized to decrease the risk for neural tube defects, thus implicating folic acid deficiency in the etiology of these anomalies.[56]

Anomalies in Aborted Fetuses

Spontaneously aborted fetuses have a higher incidence and severity of malformations than do newborns,[33] which presumably represents a higher lethality of some developmental abnormalities. Like newborns, common anomalies, such as neural tube defects and cleft lip or palate, are also frequent in aborted fetuses, although these may be more severe. Other malformations, such as cloacal exstrophy, are relatively rare in newborns but are comparatively common in aborted fetuses.

In addition to these localized and single anomalies, multiple congenital anomalies commonly occur together in aborted fetuses, including well-recognized syndromes that are caused by single genes and chromosomal abnormalities (Table 29-3).[11] It is estimated that about half of all pregnancy losses before 20 weeks' gestation have an underlying chromosomal abnormality. These losses include unrecognized early pregnancies and fetuses without an obvious structural anomaly. In this context, the most common single chromosomal abnormality is 45,X, followed by triploidy. Both conditions are more common in aborted fetuses than in newborns. The trisomies, as a group, account for more than 50% of all chromosomally abnormal pregnancy losses. The most frequent trisomy, accounting for almost one third of all trisomies, is trisomy 16, which is not found in newborns as it is lethal to the fetus.[31,33] Trisomy 21, the most common trisomy in newborns, occurs in less than 10% of all recognized trisomic conceptions. Unbalanced products of translocations account for 2% to 4% of all chromosomally abnormal fetuses and are three to six times more frequent in aborted fetuses than in newborns. As with neonates, newer genomic technology examining the chromosomes for small areas of genomic imbalance have shown an increased number of previously unrecognized deletions or amplifications of genetic material in fetuses with congenital anomalies. Analysis of the fetus's parents could be helpful in determining whether the chromosomal array finding was diagnostic of the congenital anomaly.

TABLE 29–3 Diagnoses in 375 Consecutive Cases of Pregnancy Loss

Diagnosis	≤20 Weeks (%)	>20 Weeks (%)

Minor Anomalies and Phenotypic Variants

Although major malformations often are easy to identify, minor anomalies are, by nature, more subtle and may not be appreciated unless they are specifically sought. Minor anomalies, however, can be significant, particularly because they may be part of a characteristic pattern of malformations and thus may provide clues to a diagnosis. Also, their occurrence may be an indication of the presence of a more serious anomaly. In one large study of 4305 newborns, 19.6% of the 162 infants with major malformations had three or more minor anomalies.[32] A single minor anomaly, however, was associated with a major malformation in only 3.7% of cases.[32]

Minor anomalies are most frequent in areas of complex and variable features, such as the face and distal extremities

(Table 29-4).[35] Among the most common features are lack of a helical fold of the pinna and complete or incomplete single transverse palmar crease patterns. Typical single transverse palmar crease occurs in almost 3% of normal newborns, but it appears in 45% of individuals with trisomy 21.[29]

Among the most frequent phenotypic variants, those present in 4% or more of the population, are a folded-over helix of the pinna and mongolian spots in blacks and Asians (Table 29-5).[35] Before attributing medical significance to an apparent minor anomaly or phenotypic variation, it is useful to determine whether the anomaly is present in other family members or whether it is frequent in the patient's ethnic group. It is common for isolated minor anomalies such as syndactyly of the second and third toes to be familial.

TABLE 29–4 Common Minor Malformations in Newborns (Frequency > 1:1000)

Minor Malformation	Newborns (%)
Craniofacial	
Borderline micrognathia	0.32

Racial and Ethnic Differences

The prevalence of congenital malformations varies among different racial and ethnic groups. This variation is most likely the consequence of differing genetic predispositions and variable environmental factors operating in diverse areas. Table 29-6[7,14] shows the prevalence of common major congenital malformations in white Americans, African Americans, and Chinese. It is of interest that certain anomalies are especially common in a particular race, such as polydactyly in African Americans and hypospadias and clubfoot in white Americans. Minor malformations may show an equally striking racial predisposition. Brushfield spots are common in white Americans but are rare in African Americans. Umbilical hernias, however, are common in African American infants but are relatively infrequent in white American infants. The widely varying frequencies of various traits in different races may make the determination of whether any given characteristic is considered to be a minor anomaly or a phenotypic variant strongly dependent on the race of the patient being studied. One of the best examples is mongolian spots, which occur in almost 50% of black or Asian infants but in only 0.2% of white infants.[35] Ethnic differences have also been noted for the Hispanic population, in whom there is a higher prevalence of neural tube defects, gastroschisis, and Down syndrome.[7]

EVALUATION

Every infant with a congenital anomaly should have a thorough diagnostic evaluation; without one, accurate information about the natural history of the condition and the recurrence risk for similarly affected future children cannot be

TABLE 29–6 Frequency of Common Congenital Malformations in Various Racial Groups (Per 1000)

Malformation	White Americans*	African Americans*	Chinese†
Anencephaly-myelomeningocele-encephalocele	2.4	0.9	1.5
Cleft lip and palate	1.1	0.6	1.3

provided.[17] In addition, parents usually are intensely interested in why the anomaly occurred and often harbor inappropriate guilt concerning the cause.

When a child is born with one or more anomalies, a number of considerations should guide the physician in the evaluation. The most critical factors to be considered are the detailed prenatal and family history, the dysmorphic physical examination (including careful observation and measurements of growth parameters and individual features), and the use of appropriate diagnostic tests and evaluations, particularly if there is more than one anomaly. It is important to assess whether the malformation is isolated or part of a constellation of anomalies. It is also essential to identify whether there are other major or minor anomalies, including perhaps unapparent internal malformations, and to recognize well-described patterns of malformations.[8] The severity of an anomaly can sometimes be helpful in identifying whether it may be associated with other anomalies and in predicting the prognosis for the infant. Consultation with other specialists, such as a medical geneticist, who have expertise in the evaluation of neonates with congenital anomalies, may be required.

Patient and Family History

The evaluation of an infant with congenital anomalies begins with a detailed medical, prenatal, and family history. The important goal is to identify a possible genetic predisposition, environmental factor, or other clue to the cause of the anomalies. It is useful to begin with the pregnancy to document fetal movement and vigor, complications, illnesses, maternal use of any medications, or possible exposure to teratogens, as well as the timing of all complications and exposures (see Chapter 12). In particular, information about previous prenatal ultrasound findings, maternal serum screening, and results of amniocentesis or chorionic villus sampling (if any), should be reviewed. The extent of smoking and alcohol consumption should be determined, and every mother should be asked about illicit drug use.

To identify other potentially affected family members and obtain clues to an etiology, a detailed three- to four-generation family history, charted in a concise manner in the form of a pedigree, should be constructed, using squares for male and circles for female members. Horizontal lines indicate genetic union, and vertical lines indicate genetic descent. All abortions and stillbirths should be noted. A question always should be specifically asked about possible parental consanguinity. A simple way to inquire is to ask if the families of the affected child's parents are related in any way. If so, the charting should indicate the exact relationships. The presence of other relatives with congenital anomalies of any type or with growth or developmental abnormalities should be recorded along with other pertinent information, such as the maternal and paternal ages and the nature of the anomaly. Family photographs are often very useful in clarifying questions of possible unusual facial features. The pedigree should, at a minimum, include all siblings and parents of the proband as well as aunts, uncles, cousins, and grandparents. In the case of possible dominant or X-linked disorders, a more extensive pedigree may be needed.[54]

Physical Examination

(See also Chapter 27)

The goal of the physical examination of an infant with congenital anomalies is to determine whether an anomaly is isolated or to detect a recognizable pattern of malformations so that a specific etiologic determination can be made. In addition, careful attention must be directed not only to an exact description of the major anomalies but also to apparent minor anomalies or variations. Distinctive physical features may become clues in identifying the cause of multiple congenital anomalies; therefore, a detailed inspection of various features of external anatomy and measurement of them when appropriate should be performed. The overall body size measurements of length, weight, and head circumference should be compared with gestational norms. Normal measurements of many face and body characteristics can be found in a number of resources.[23,29] Objective description of anomalous features allows for appropriate use of resources or consultants. In this section, an outline of this external examination is presented by region or structure, and certain helpful points, as well as aspects of the differential diagnosis, are discussed. Greater detail in regard to examination and abnormalities of various organ systems is given in other relevant chapters in this book, but the clinician should pay particular attention to neurologic and cardiac signs and symptoms. We also refer the reader to various resources in which the anomalies and syndromes mentioned in this section are discussed at length.[1,20,29,52]

SKIN

(See also Chapter 52)

Normal infant skin, particularly when exposed to cold temperatures, shows a marbling pattern termed *cutis marmorata* or *livedo reticularis*. In rare instances, this pattern may be unusually prominent and familial, inherited as an autosomal dominant trait. A similar prominent pattern may occur in those with trisomy 21, hypothyroidism, or Cornelia de Lange syndrome.

A variety of lesions with altered pigmentation may provide useful clues to a diagnosis. Café-au-lait spots are characteristic of neurofibromatosis, but they also occur in other conditions and may be isolated, especially in darkly pigmented infants. Hypopigmented macules may be the earliest manifestation of tuberous sclerosis in the young infant. Multiple irregular pigmented lesions arranged in whorls are suggestive of incontinentia pigmenti, but this disorder usually presents initially with a vesicular rash. An angiomatous patch over one side of the face may be an isolated anomaly or part of Sturge-Weber syndrome. More than one skin hemangioma should raise suspicion of internal vascular lesions.

Generalized edema may obscure many minor anomalies, making diagnosis difficult. Turner syndrome, trisomy 21, and Noonan syndrome should be considered in newborns with generalized edema. The texture of the skin also can assist the clinician with a syndromic diagnosis because thick or coarse skin is characteristic of Costello syndrome, and abnormal distribution of fatty tissue can be seen in congenital disorders of glycosylation.

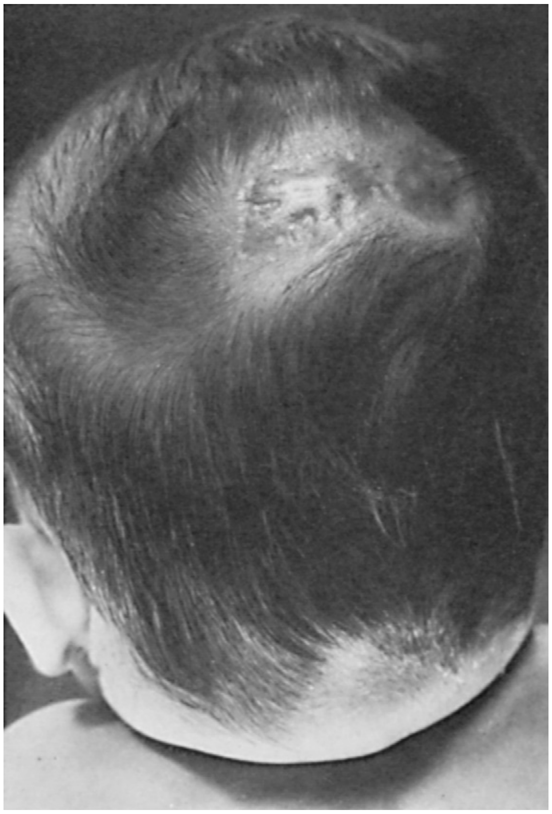

Figure 29–2. Scalp lesions in trisomy 13.

HAIR

The relative sparseness or prominence of body hair should be noted. Sparse hair is characteristic of an ectodermal dysplasia, but it does occur in other syndromes, such as cartilage-hair hypoplasia and oculodentodigital syndrome. Generalized hirsutism is typical of Cornelia de Lange syndrome, fetal hydantoin syndrome, and fetal alcohol syndrome, but it also may occur in those with trisomy 18. It also may be an ethnic (Hispanic, Middle-Eastern, American Indian) or familial characteristic.

Abnormal scalp hair patterns may reflect underlying brain abnormalities. In microcephaly, there may be a lack of the normal parietal whorl, or the whorl may be displaced more centrally or posteriorly. In addition, the frontal hair may show a prominent upsweep. A low posterior hairline occurs with a short or webbed neck, as in Turner syndrome and Noonan syndrome. Punched-out scalp lesions in the parietal occipital area (aplasia cutis congenita) are typical of trisomy 13 or may be seen in isolation and may be familial (Fig. 29-2).

HEAD

(See also Chapter 40, Part 7)

The size of the head, measured by the maximal head circumference, and the sizes of the anterior and other fontanelles should be compared with those of appropriate standards. Head size varies with age, sex, and racial group and correlates with body size. Macrocephaly as an isolated anomaly often is familial and inherited in an autosomal dominant fashion; therefore, determining the head circumferences of the parents is helpful. However, macrocephaly may be a manifestation of several disorders, including hydrocephaly and various conditions affecting the skeletal system, such as achondroplasia, or overgrowth syndromes, such as the PTEN hamartoma tumor syndrome. Microcephaly can also be familial, either autosomal dominant or recessive, but it is more commonly a manifestation of many syndromes that result in mental retardation. Large fontanelles occur in hypothyroidism; in trisomies 21, 18, and 13; in peroxisomal disorders like Zellweger syndrome, and in many bone disorders, such as hypophosphatasia and cleidocranial dysostosis. A small anterior fontanelle may be a sign of failure of normal brain growth.

The normal shape of the head may vary from an increase in the anteroposterior diameter (dolichocephaly) to a decrease in this dimension (brachycephaly). Premature infants and those with trisomy 18 characteristically have dolichocephaly (Fig. 29-3A), and hypotonic infants often develop dolichocephaly over time, but either type of head shape may be of familial or racial origin. Many Asian and American Indian infants, for example, have strikingly brachycephalic heads.

Premature fusion of cranial sutures (craniosynostosis) results in an abnormal configuration in head shape. Various types occur depending on the sutures involved (see Chapter 40, Part 7). Torticollis or abnormal mechanical forces in utero can cause asymmetric head shape (plagiocephaly). A common anomaly in head shape is frontal bossing, which is frequent in some skeletal dysplasias such as achondroplasia and in some cases of hydrocephaly.

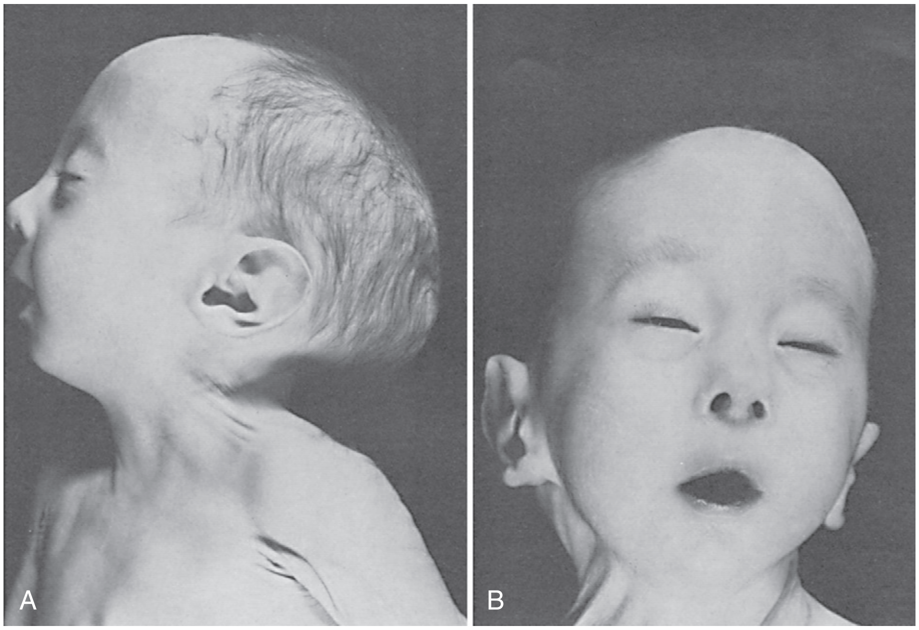

Figure 29–3. Trisomy 18. **A**, Note dolichocephaly. **B**, Note small mouth and anomalous ears.

FACE

The face is composed of a series of structures, each demonstrating considerable normal variation and providing a distinctive and unique appearance to every human. Because examination of the face is both complex and important to establishing an etiology of anomalies, a systematic approach is necessary. It is never sufficient merely to describe the face as “unusual” nor appropriate to describe the face as “funny looking.” Specific abnormalities should be analyzed and quantified, when appropriate, even though an overall gestalt impression may suggest a diagnosis in some cases. Recall that lack of resemblance to other family members may be an indicator of an underlying condition.

EYES

Hypotelorism occurs when the eyes are unusually close together; hypertelorism occurs when the eyes are too far apart. Clinically, hypotelorism and hypertelorism are defined by the interpupillary distance, which may be estimated in a relaxed patient by measuring between the midpoints of the pupils. It is usually impossible to measure the interpupillary distance of a newborn; therefore, two other relevant and useful measurements that are easier to obtain are the inner canthal distance and the outer canthal distance. Telecanthus is an increase in the inner canthal distance, and it may occur in the absence of hypertelorism, such as in Waardenburg syndrome type I. There are other factors that may create an illusion of hypertelorism, such as epicanthal folds and a flat nasal bridge; therefore, a subjective impression should always be confirmed by measurement of all three distances, if possible. From the prognostic and diagnostic points of view, it is important to identify hypotelorism because often it is associated with holoprosencephaly, a major malformation of the central nervous system that usually is associated with severe disturbance of brain function and early death. Holoprosencephaly can be isolated or can be part of trisomy 13 (Fig. 29-4) or occasionally other syndromes. Hypertelorism, however, occurs in a number of syndromes, such as frontonasal dysplasia, and even when it is severe, it is less likely to be related to an underlying brain malformation. Comparison with parents’ eye distances is important. Figures 29-5 and 29-6 illustrate hypertelorism with midline facial anomalies.

Epicanthal folds are a feature of normal fetal development, and they may be present in normal infants. They are characteristic in trisomy 21 (Fig. 29-7A and B), but they occur in many other malformation syndromes, especially in those that include a flat nasal bridge.

Normally, an imaginary line through the inner and outer canthi should be perpendicular to the sagittal plane of the face. An upward slant to the palpebral fissure is seen in trisomy 21 (see Fig. 29-7A and B), and a downward slant is seen in mandibulofacial dysostosis (see Fig. 29-7C) and Noonan syndrome. Both types of slant can be part of a number of other syndromes.

Palpebral fissure length is measured from the inner canthus to the outer canthus. Short palpebral fissures may occur in association with other ocular anomalies, such as microphthalmia, and they are characteristic of syndromes such as fetal alcohol syndrome (see Fig. 29-1) and trisomy 18 (see Fig. 29-3B).

A coloboma is a developmental defect in the normal continuity of a structure, and it often is used in reference to the eye. Colobomas may involve the eyelid margin, as those seen in Treacher Collins syndrome (see Fig. 29-7C), or the iris and retina, as those seen in CHARGE syndrome. Identification of a coloboma should lead to a formal ophthalmologic evaluation.

Synophrys, or fusion of the eyebrows in the midline, is common in hirsute infants, and it may also be familial in some instances. The Cornelia de Lange syndrome is strongly associated with synophrys.

Anomalies of the internal eye structure are discussed in Chapter 53.

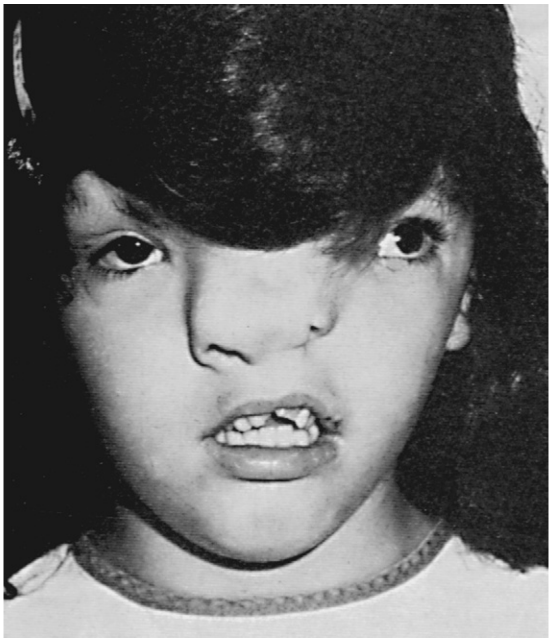

Figure 29–5. Frontonasal dysplasia with hypertelorism and bifid nose.

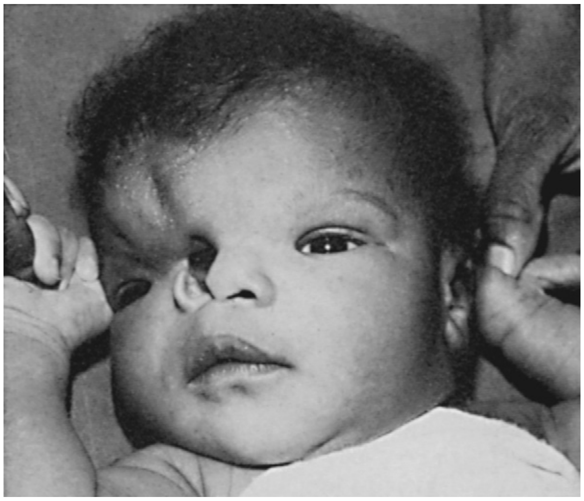

Figure 29–6. Frontonasal dysplasia with nasal cleft.

EARS

The external ear, or pinna, commonly shows great variation that can be identified by a number of anatomic landmarks. These should be described and measured when evaluating the anomalous ear. These landmarks include the helix, antihelix, tragus, antitragus, external meatus, and lobule (Fig. 29-8). If the ears appear to be large or small, they should be measured by obtaining the maximal length of the pinna from the lobule to the superior margin of the helix. Preauricular tags or pits may be isolated or associated with other abnormalities of the pinna (Fig. 29-9).

The ears are low set when the helix joins the head below a horizontal plane passing through the outer canthus perpendicular to the vertical axis of the head (Fig. 29-10). It is critical that this condition be assessed with the head in vertical alignment with the body because any posterior rotation of the head can create an illusion of low-set ears. In most instances, the relative placement of the ears is more a function of head shape and jaw size than of an intrinsic anomaly of the ear.

When the vertical axis of the ear deviates more than 10 degrees from the vertical axis of the head, the ears are posteriorly rotated. This anomaly often is associated with low-set ears and represents a lag in the normal ascent of the ear during development (Figs. 29-11 and 29-12). Care should

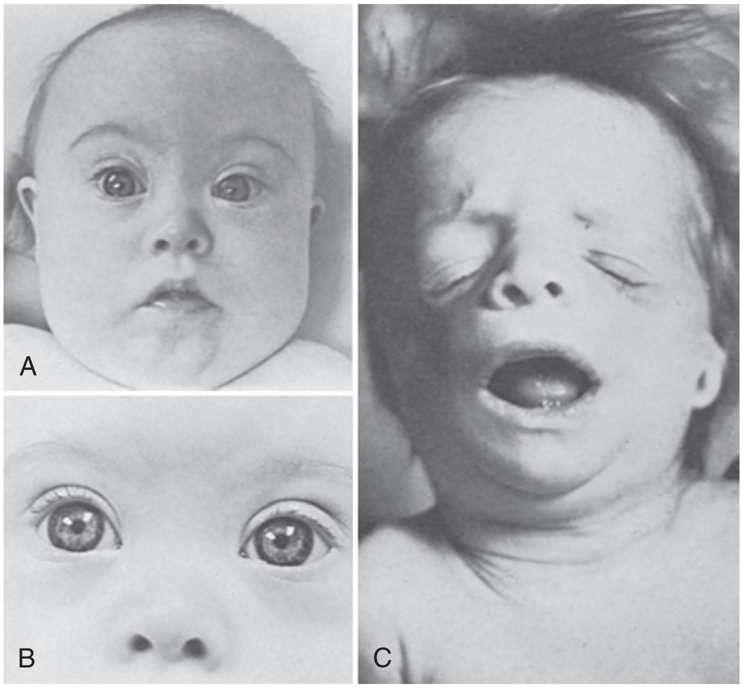

Figure 29–7. **A**, Trisomy 21. Note epicanthal folds and mongoloid slant of eyes. **B**, Enlargement of eyes of patient in A. Note Brushfield spots on irides. **C**, Mandibulofacial dysostosis (Treacher Collins syndrome) with antimongoloid slant of eyes. Note coloboma, or notch, in left eyelid.

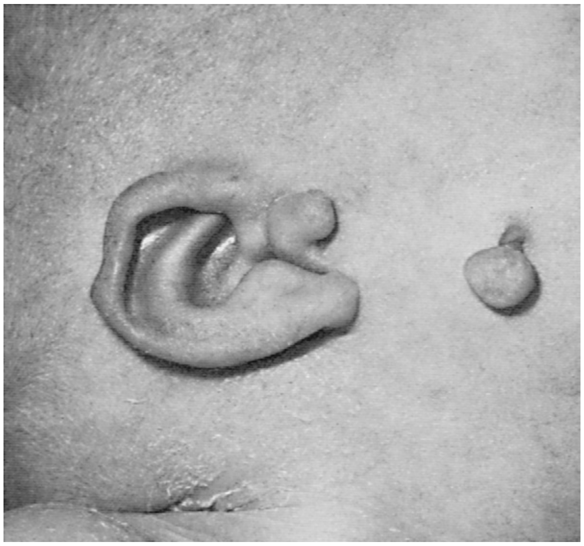

Figure 29–9. Preauricular tags with malformed pinna.

be taken when examining neonates in the intensive care unit because tape used to secure intubation or nasal-gastric tubes can give the false impression of posteriorly rotated ears.

Any significant abnormality of the external ear may be an indication of additional anomalies of the middle or inner ear and may be associated with hearing loss; therefore, an early hearing assessment is indicated in such cases (see Chapter 42). Figure 29-13 illustrates a patient with hemifacial microsomia, whose findings include a severely malformed pinna and an absent ear canal. This is one condition in which an early hearing assessment is essential because hearing loss is likely.

NOSE

The nose, like the external ear, shows great individual variation, but certain alterations in shape are frequent in malformation syndromes involving the face. The nose may be unusually thin with hypoplastic alae nasi, as in Hallermann-Streiff syndrome, or it may be unusually broad, as in frontonasal dysplasia (see Fig. 29-5). A depressed nasal bridge with an upturned nose occurs in many skeletal dysplasias, such as achondroplasia. When the depression is severe, the nostrils may appear to be anteverted, and the nose may appear to be shortened. A hypoplastic nose is often syndromic, and a nose with a single nostril is highly suggestive of holoprosencephaly (see Fig. 29-4).

MOUTH

(See also Chapter 44, Part 6)

The mouth is a complex structure with component parts that each require separate evaluation. The size and shape of the mouth may be altered. A small mouth, or microstomia, should be noted; it occurs in trisomy 18 (see Fig. 29-3). Macrostomia,

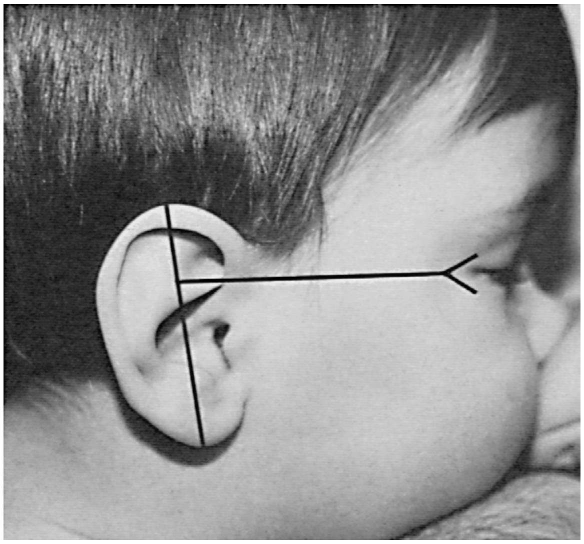

Figure 29–10. Normal pinna and its orientation with respect to eyes.

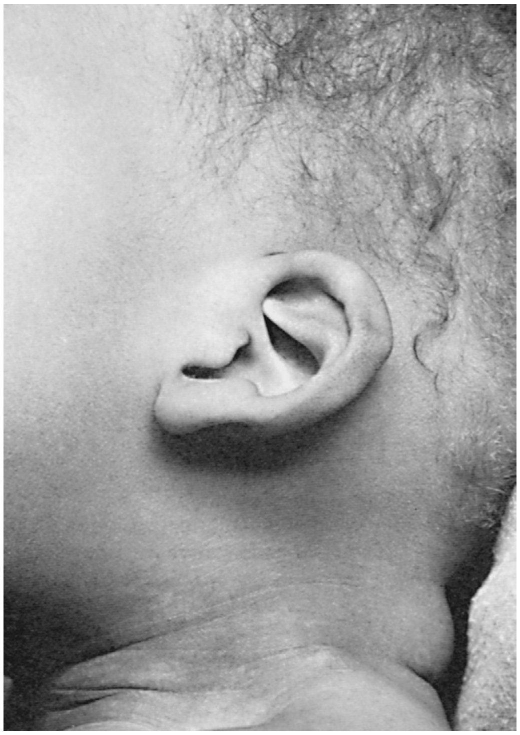

Figure 29–11. Abnormal pinna that is low set and posteriorly rotated in patient with Smith-Lemli-Opitz syndrome.

a large mouth, should be noted as well; it may be present in such conditions as mandibulofacial dysostosis (see Fig. 29-7C). Severe macrostomia may result from a lateral facial cleft. The corners of the mouth may be downturned, as in Prader-Willi syndrome and other conditions with hypotonia. An asymmetric face during crying occurs with congenital deficiency in the depressor anguli oris muscle on one side, and this may be associated with other abnormalities, such as hemifacial microsomia and velocardiofacial/DiGeorge syndrome.

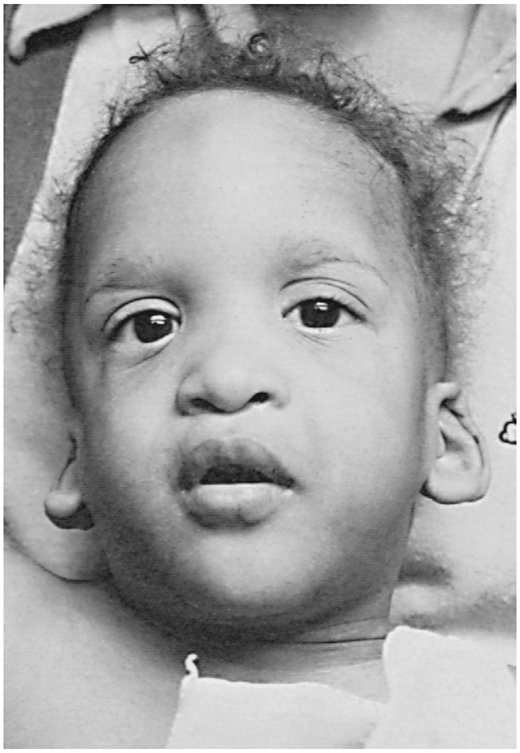

Figure 29–12. Facial view of patient in Figure 29-11.

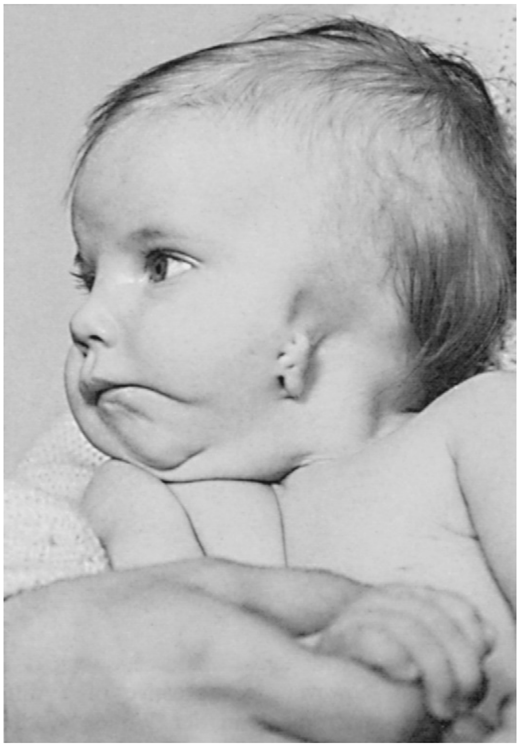

Figure 29–13. Hemifacial microsomia showing mandibular hypoplasia, severely malformed pinna, and absent ear canal.

Prominent, full lips occur in various syndromes, including Williams syndrome. A thin upper lip may be seen in Cornelia de Lange syndrome and in fetal alcohol syndrome (see Fig. 29-1).

A cleft upper lip is usually lateral, as in the common multifactorial cleft lip (or palate) anomaly, occurring in the position of one of the philtral ridges. The presence of pits in the lower lip associated with a cleft lip or palate, however, is suggestive of Van der Woude syndrome, which is inherited in an autosomal dominant manner. A median cleft lip is very suggestive of holoprosencephaly (see Fig. 29-4A). In fact, there are many diverse syndromes with cleft lip or palate that are important to identify because they may have other associated malformations and relatively high genetic risks for recurrence. Therefore, it is particularly important to evaluate the infant with cleft lip or palate carefully for evidence of other malformations to give accurate recurrence risk and prognostic information to the family.

Isolated cleft palate is different genetically from cleft lip.[44] Mild forms of cleft palate are represented by submucosal clefts, pharyngeal incompetence with nasal speech (velopharyngeal insufficiency), and bifid uvula. A high arched palate may occur normally, but it is also a feature of many syndromes, especially if hypotonia or another long-standing neurologic abnormality is present. Hypertrophied alveolar ridges are apparent in the palate along the inner margin of the teeth, and they are suggestive of Smith-Lemli-Opitz syndrome (Fig. 29-14) if seen in an infant.

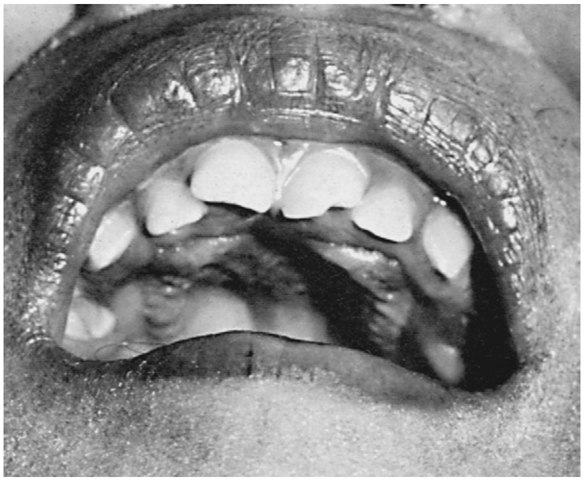

Figure 29–14. Prominent alveolar ridges in patient with Smith-Lemli-Opitz syndrome.

Macroglossia may be relative, as in the Pierre Robin malformation sequence, in which the primary abnormality is mandibular hypoplasia. In other cases, such as hypothyroidism, Beckwith-Wiedemann syndrome, and Down syndrome, the tongue protrudes and is enlarged. A cleft or irregular tongue or oral frenula occurs in various syndromes such as the orofaciodigital syndromes.

The lower portion of the mouth is formed by the mandible, which in young infants is relatively small. An excessively small mandible is termed *micrognathia*, which is a feature of many syndromes. It is a characteristic of the Pierre Robin sequence, which consists of the triad of micrognathia, glossoptosis, and a U-shaped cleft palate, as opposed to the common V-shaped cleft. A typical patient is shown in Figure 29-15. The Pierre Robin sequence may be part of a syndrome, such as Stickler syndrome (hereditary arthro-ophthalmopathy), and thus other anomalies and a family history must be sought. In other syndromes, the maxilla likewise may be hypoplastic, decreasing the prominence of the upper cheeks (malar hypoplasia).

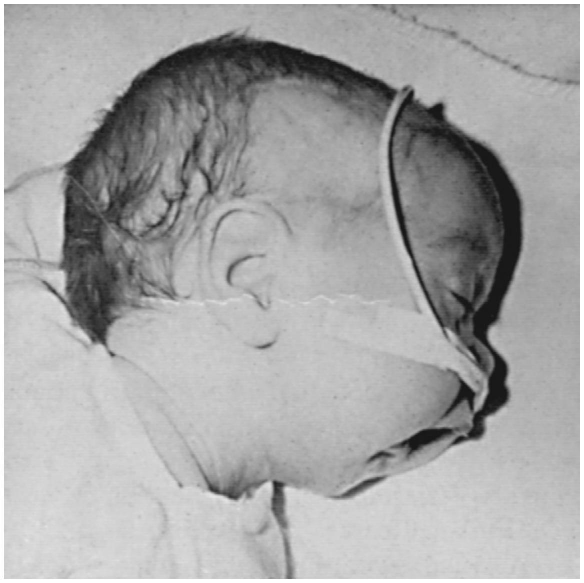

Figure 29–15. Micrognathia in Pierre Robin sequence.

NECK

The neck may be short, and limitation of rotation should raise the suspicion of fusion of cervical vertebrae, as in a Klippel-Feil anomaly. Excessive skinfolds are characteristic of Turner syndrome (Fig. 29-16), Noonan syndrome, and Down syndrome. In these examples, the excess nuchal skin often represents resolution of a cystic hygroma that was present prenatally.

CHEST

The thoracic cage may be unusually small as part of a skeletal dysplasia, such as thanatophoric dysplasia (Fig. 29-17) or Jeune asphyxiating thoracic dystrophy. The sternum itself may be unusually short, which is typical in trisomy 18, or it may be altered in shape, as is seen in pectus excavatum or pectus carinatum. The latter anomalies are commonly seen in a variety of skeletal dysplasias and connective tissue disorders (see Chapter 44, Part 5).

ABDOMEN

(See also Chapter 47)

Hypoplasia of the abdominal musculature may occur in association with intrauterine bladder outlet obstruction and other anomalies of the urogenital system. It results in a characteristic prune-belly appearance in Eagle Barrett syndrome (see Chapter 51). An omphalocele, in which abdominal contents protrude through the umbilical opening, may be part of the Beckwith-Wiedemann syndrome (see Chapter 49, Part 1) or chromosomal abnormalities such as trisomy 13. Gastroschisis, however, is usually an isolated disruption in which the abdominal contents protrude through the periumbilical

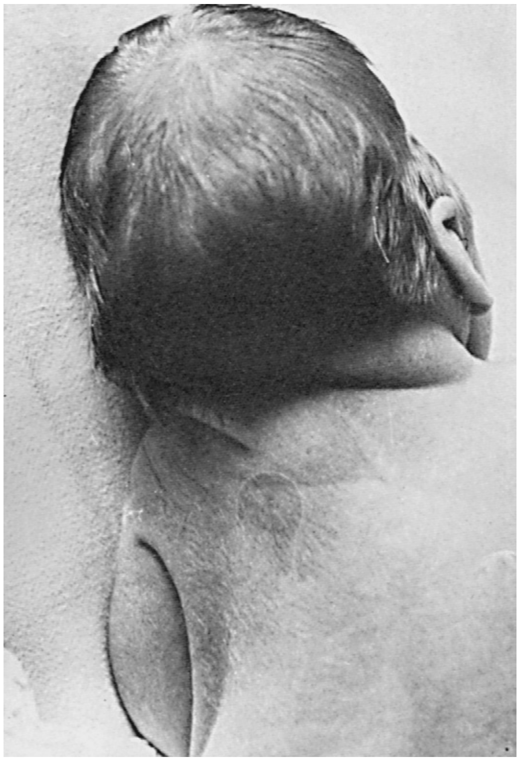

Figure 29–16. Excess skinfolds of the neck in patient with Turner syndrome.

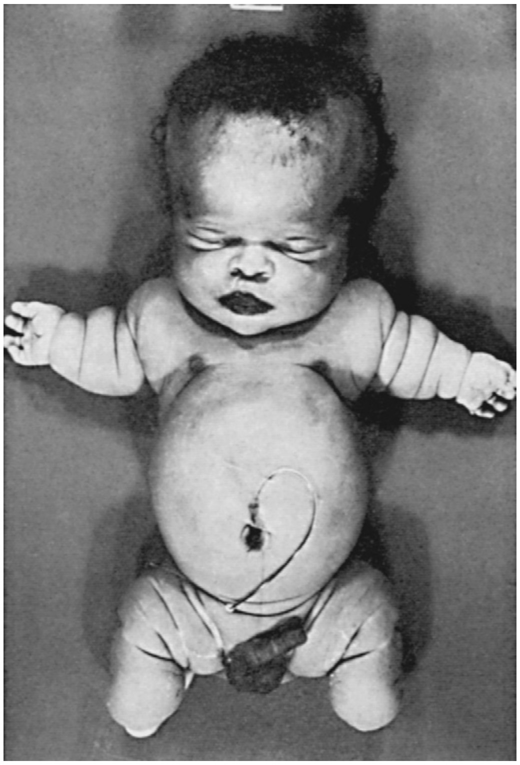

Figure 29–17. Thanatophoric dwarf. Note short limbs and narrow thoracic cage.

abdominal wall. Anomalies of a more minor nature, such as inguinal or umbilical hernias, occur in normal infants, but they are more frequent in various syndromes, particularly in connective tissue disorders.

ANUS

(See also Chapter 47)
Imperforate or displaced anus may be isolated or may occur as the mildest expression of a caudal regression sequence, in which other anomalies such as sacral dysgenesis are seen. It is most commonly part of a constellation of anomalies, such as the VATER or VACTERL association. It also can be seen in a number of chromosomal abnormalities or as part of diabetic embryopathy.

GENITALIA

(See also Chapter 49, Part 4)
Hypogenitalism can be seen in association with hypotonia in Prader-Willi syndrome or with low-set dysplastic ears, syndactyly of the toes, and thickened alveolar ridges in Smith-Lemli-Opitz syndrome. Genital ambiguity is associated with renal anomalies and an increased risk for Wilms tumor in Denys-Drash syndrome. Virilization may be associated with 21-hydroxylase deficiency, which requires urgent management of adrenal insufficiency.

SPINE

(See also Chapter 40)
Among the most common congenital anomalies are the neural tube defects, which involve abnormalities of the central nervous system along with defects in the associated bony structures. Minor external anomalies, particularly of the lower spine, include unusual pigmentary lesions, hair tufts, dimples, and sinuses. Some of these changes, such as hair tufts and sinuses above the gluteal cleft, may be an indication of a more significant deeper anomaly and require further evaluation, such as magnetic resonance imaging.

EXTREMITIES

Extremities may be relatively long, as occur in Marfan syndrome or homocystinuria, or unusually short, as occur in a diverse group of skeletal dysplasias, the most common being achondroplasia. A simple guide to evaluating relative extremity length is to determine where the fingertips are in relation to the thighs when the upper extremities are adducted alongside the body. In the normal infant, the fingertips fall below the hip joint in the midthigh region. When the upper extremities are short, they align with the hip joint or above (see Fig. 29-17); when they are relatively long, they may reach the knees. A more precise and useful bedside measurement is to determine the ratio of the upper segment to the lower segment. The distance from the pubis to the heel with the leg fully extended constitutes the lower segment. By subtracting the lower segment measurement from the total length, one obtains the upper segment. In normal newborns, the ratio of the upper segment to the lower segment is about 1.7, and the ratio decreases with age to about 1.0 in the adult. A high ratio suggests relative shortening of the extremities, and a low ratio implies either unusually long extremities or a foreshortened trunk, as may occur in spondyloepiphyseal dysplasia.

Paired extremities may be asymmetric in either length or overall size, suggesting either atrophy of one or hypertrophy of the other. The distinction may be difficult to make at times, although it is often evident if an extremity is unusually large or excessively small. Hypertrophy of limbs may be a manifestation of Beckwith-Wiedemann syndrome or Klippel-Trenaunay-Weber syndrome. Isolated hemiatrophy may occur with long-standing corticospinal tract damage as well, as in Russell-Silver syndrome. It is important to identify hemihypertrophy because individuals with this finding are at increased risk for intra-abdominal tumors, such as Wilms tumor, and thus require close monitoring throughout infancy and childhood.

Foreshortening of long bones leads to various limb abnormalities, depending on the segments involved. A number of terms have been used to describe such anomalies. *Rhizomelia* denotes proximal shortening of the limbs, such as those in achondroplasia. *Mesomelia* refers to shortening of the middle segment, and *acromelia* refers to relative shortening of the hands or feet. A shortened forearm with secondary prominence of skinfolds in a newborn with thanatophoric dysplasia is shown in Figure 29-18.

The hands and feet have epidermal ridges and creases forming a variety of configurations. Normally, there are two deep transverse palmar creases that do not completely cross the palm. In various conditions, such as trisomy 21, there may instead be a single transverse palmar crease. Single palmar creases may be completely transverse across the palm or may be bridged or incomplete (Fig. 29-19A and B). They may become more apparent when the palm is slightly flexed. A single phalangeal crease on the fifth finger, instead of the normal two, occurs as a consequence of a hypoplastic middle phalanx and results in clinodactyly (incurving of the digit). This is frequently seen in trisomy 21 (see Fig. 29-19C) and in a number of other conditions.

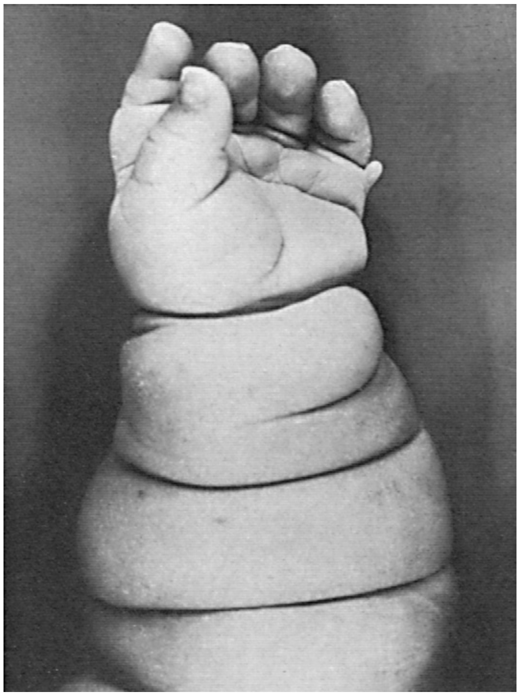

Figure 29–18. Forearm and hand of patient in Figure 29-17. Note rudimentary postaxial polydactyly.

The foot also has ridge patterns. A sandal pattern of deep furrows is typical of mosaic trisomy 8 (Fig. 29-20). Figure 29-21 illustrates the increased separation of the first and second toes and a prominent interdigital furrow in trisomy 21.

Historically, dermatoglyphics, the study of configurations of the characteristic ridge patterns of the volar surfaces of the skin, was sometimes used to aid in the diagnosis of the newborn with congenital anomalies. The scope of this subject is beyond that of this chapter, and the reader is referred to other sources.[43]

The hands and feet may be enlarged as a result of lymphedema. This is characteristic of infants with Turner or Noonan syndrome, in which the dorsum of the hands and feet may have a puffy appearance (Fig. 29-22). Congenital lymphedema can also be an autosomal dominantly inherited condition with variable expressivity.

Rocker-bottom feet (Fig. 29-23) is a term used to describe a prominent heel and a loss of the normal concave longitudinal arch of the sole. This feature is common in trisomy 18 and other syndromes.

Significant anomalies of the underlying structure produce alterations in the normal form of the hands and feet. Such abnormalities may be classified into the following categories: absence deformities, polydactyly, syndactyly, brachydactyly, arachnodactyly, and contracture deformities (see Chapter 54).

Absence anomalies are of various types, and the etiology and possible associated malformations vary with the type. Congenital absence of an entire hand is termed *acheiria*, and absence of both hands and feet is *acheiropodia*. *Ectrodactyly* refers to a partial or total absence of the distal segments of a hand or foot, with the proximal segments of the limbs more or less normal. All such anomalies are examples of terminal transverse defects and may occur sporadically or as part of a syndrome. The term *ectrodactyly* is frequently misused for the lobster-claw anomaly, which is best described as split hand/split foot. In this anomaly, the central rays are deficient, and there is often fusion of the remaining digits. Split hand/split foot may be seen in isolation, when it is of autosomal dominant origin, or it may be seen with other anomalies.

It is useful to determine whether the defects involve primarily the radial, or preaxial, side of the limb or the ulnar, or postaxial, side. For example, blood dyscrasias such as Fanconi anemia and the thrombocytopenia-absent radius syndrome commonly involve radial deficiency (see Chapter 46).

Polydactyly refers to partial or complete supernumerary digits and is one of the most common limb malformations. Postaxial polydactyly is more frequent than preaxial, particularly in African Americans (Fig. 29-24). As an isolated anomaly, polydactyly may be inherited as an autosomal dominant trait. It also may be a manifestation of a multiple malformation syndrome. Postaxial polydactyly may occur in a variety of syndromes, including trisomy 13 (Fig. 29-25), chondroectodermal dysplasia, Meckel-Gruber syndrome, and Bardet-Biedl syndrome. Preaxial polydactyly is characteristic of Carpenter syndrome and Majewski short rib–polydactyly syndrome.

Syndactyly refers to fusion of digits; it is usually cutaneous, but it may involve bone. Minimal syndactyly of the

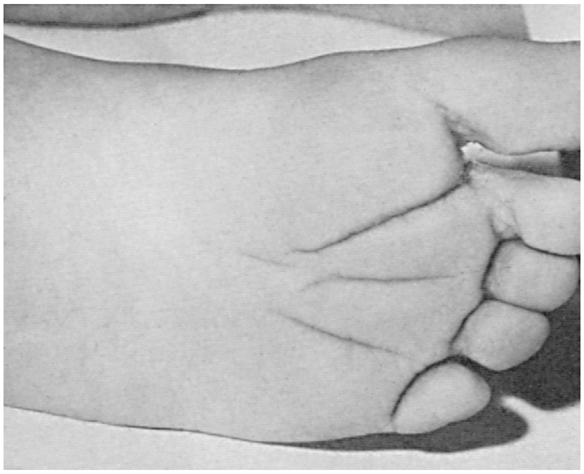

Figure 29–20. Sandal line furrows in trisomy 8.

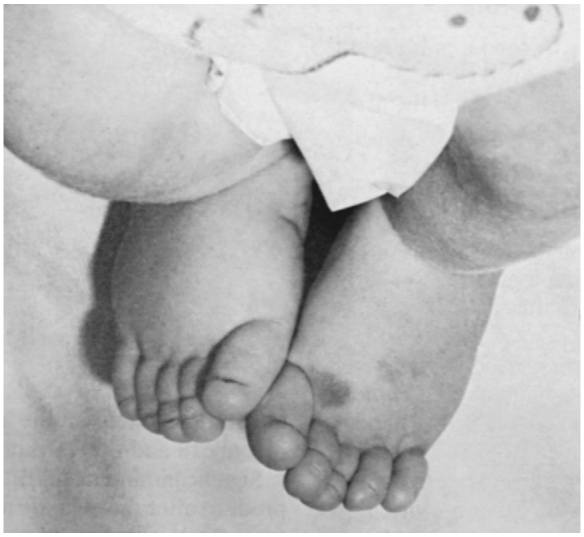

Figure 29–22. Dorsal edema of feet in patient with Turner syndrome.

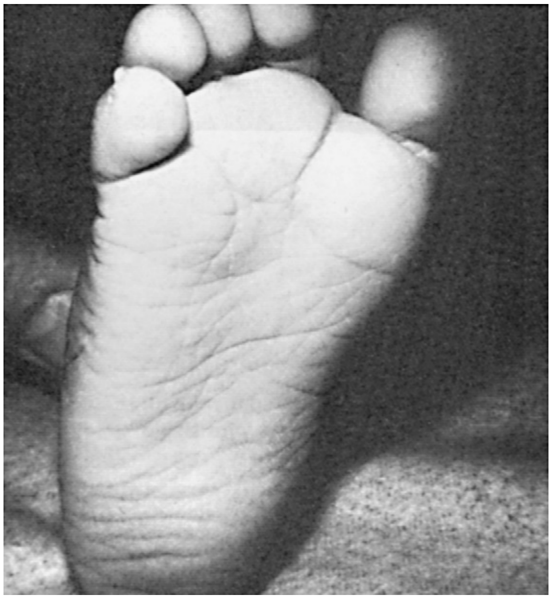

Figure 29–21. Trisomy 21. Note increased separation of first and second toes.

second and third toes is common in normal newborns. More extensive syndactyly is shown in Figure 29-26 and can be seen in trisomy 21 and Smith-Lemli-Opitz syndrome. As an isolated anomaly, different clinical types may be distinguished, but each of them is inherited as an autosomal dominant trait with variable expressivity and incomplete penetrance. Extensive syndactyly often is part of a syndrome, and typical examples include some of the craniosynostosis conditions, such as Apert and Pfeiffer syndromes.

Brachydactyly refers to shortening of one or more digits owing to anomalous development of any of the phalanges, metacarpals, or metatarsals. Various clinical types may be distinguished, but most isolated forms of brachydactyly are inherited in an autosomal dominant fashion. Brachydactyly is also a component of numerous disorders, including skeletal dysplasias such as achondroplasia and syndromes such as Albright hereditary osteodystrophy and Down syndrome (see Fig. 29-19C).

Arachnodactyly refers to unusually long, spider-like digits, and it is characteristic but not invariable in Marfan syndrome and homocystinuria. The appearance of brachydactyly and

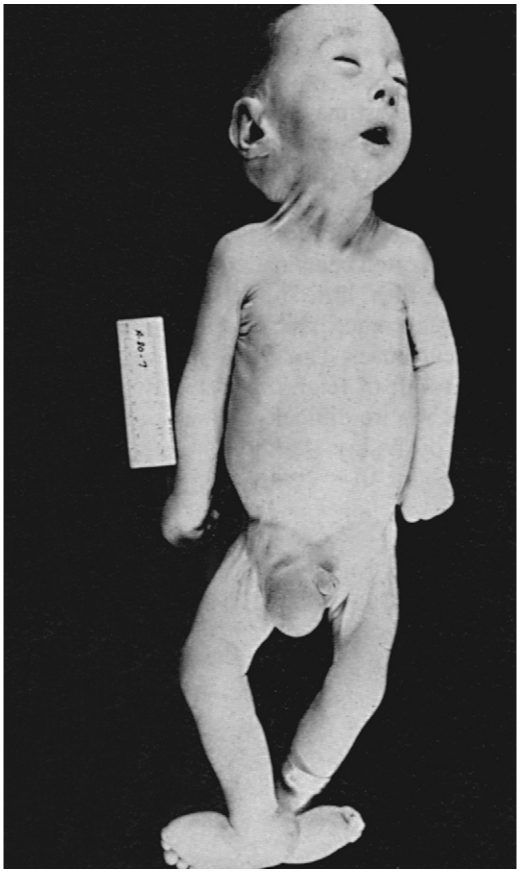

Figure 29–23. Trisomy 18. Note right hydrocele and rocker-bottom feet.

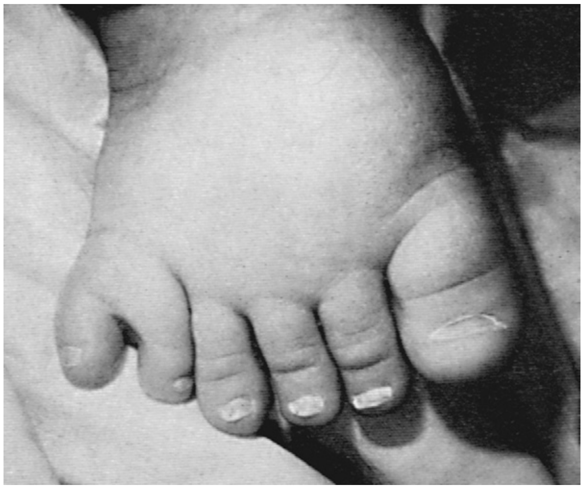

Figure 29–24. Postaxial polydactyly.

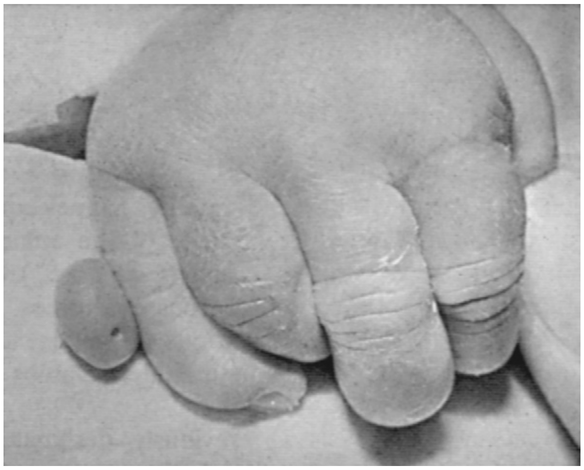

Figure 29–25. Postaxial polydactyly in trisomy 13.

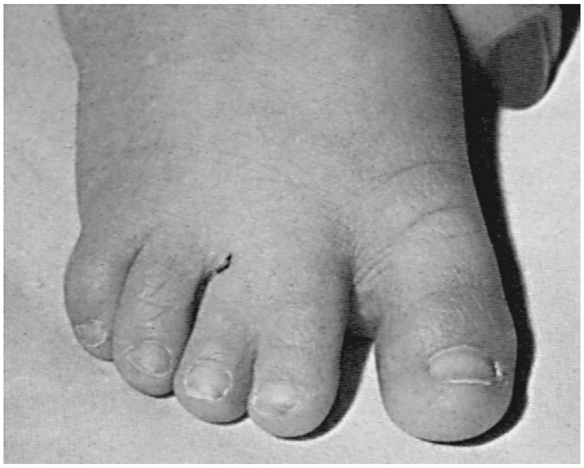

Figure 29–26. Syndactyly between second and third toes.

arachnodactyly can be confirmed by measuring and determining the ratio of middle finger to total hand length, which is normally about 0.43 in the newborn.

A variety of congenital joint deformities involving the limbs may occur. Arthrogryposis, multiple congenital contractures, is most often sporadic and may be associated with oligohydramnios or may be the result of some underlying neuromuscular abnormality, such as spinal muscular atrophy. Talipes equinovarus or calcaneovalgus deformities of the ankle are common isolated joint contractures (see Chapter 54). Contractures also may occur in numerous syndromes. Joint hypermobility is frequent in various connective tissue disorders, such as Marfan and Ehlers-Danlos syndromes, and can also be seen in a number of multiple anomaly syndromes such as Kabuki syndrome.

Clinodactyly, as discussed previously, designates an incurving of a digit, most commonly of the fifth finger. This condition is frequent in trisomy 21 and other syndromes (see Fig. 29-19C). A characteristic clinodactyly involving the fourth and fifth fingers radially and second finger in an ulnar direction occurs in trisomy 18 (Fig. 29-27) or, less often, in trisomy 13.

Camptodactyly is irreducible flexion of the digits. In the hand, it usually involves the fifth finger, but it may affect other fingers as well. Isolated camptodactyly may be inherited as an autosomal dominant trait. Camptodactyly also may be part of a syndrome such as trisomy 8, trisomy 10q, and Freeman-Sheldon syndrome.

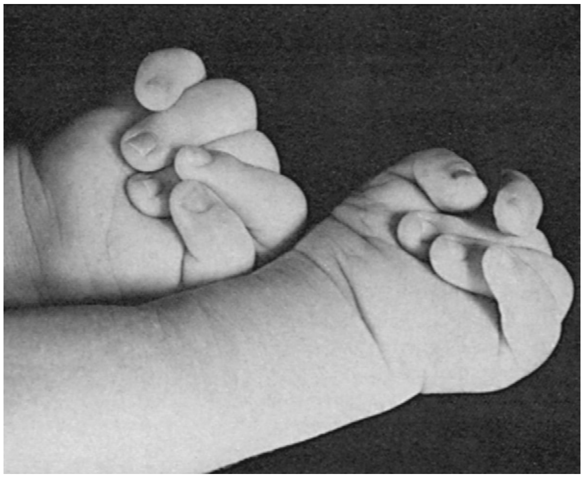

Figure 29–27. Trisomy 18. Note characteristic clinodactyly of second, fourth, and fifth fingers.

Evaluation of the Stillborn

Evaluation of the stillborn is essential to the diagnostic workup and is similar to that of the live-born infant. If this important function is not adequately performed, the family is left with little understanding of the nature and etiology of the anomaly, the recurrence risk, and methods of preventing future occurrences. Further, the grieving process, a natural consequence of fetal loss, can be more difficult without an understanding of the cause of the loss. In addition to the obvious role of the pathologist to learn as much as possible from the examination of the aborted fetus, the clinician is essential in encouraging the family to allow fetal evaluation and to allow the pathologist to conduct it. The clinician also should direct additional testing and meet with the family when the evaluation is complete to ensure that the family receives medical and genetic counseling. These evaluations are generally done by the perinatologist or neonatologist, and it is reasonable to assume that before 20 weeks' gestation, responsibility of pregnancy loss evaluation rests with the perinatologist, and after this date, it falls to the neonatologist.

Pregnancy loss before 20 weeks occurs in at least 12% to 15% of all pregnancies and in 1% to 2% of pregnancies after 20 weeks, when it is usually called *stillbirth*.[11,38,50] It is optimal for each hospital to develop a protocol for evaluating fetal loss, including which fetuses to study and which evaluations are appropriate.[10] A thorough surface examination by the clinician is useful to identify minor anomalies that may not be apparent to the pathologist as rigor mortis sets in. If indicated, a sample of blood or skin should be obtained as soon as possible under sterile conditions for chromosome analysis. Skin can be placed in viral culture media or sterile saline and sent to the laboratory for fibroblast culture. Cells from the fetal side of the placenta may grow when macerated fetal tissue may not. Examination of the stillborn and the placenta by the pathologist may identify internal anomalies that lead to a definitive diagnosis.

DIAGNOSTIC TESTING AND INDICATIONS

Once a thorough history has been taken and a physical examination has been performed, the clinician should identify those features that are most unique to the neonate. Sometimes a pattern is readily recognized, such as Down syndrome in a child with an atrioventricular canal, hypotonia, palpebral fissures that slant upward, small squared ears, and fifth finger clinodactyly. However, a review of reference texts often is required to determine whether the findings represent a previously recognized malformation syndrome.[9,29] A clinical geneticist may be especially helpful at this point.

The following laboratory and imaging studies may be indicated to aid in making an accurate diagnosis. In many cases, a diagnosis does not become apparent until later in life as the physical features change and other structural or functional abnormalities become apparent.[37] Parents should be counseled about this possibility and that even though a diagnosis may not be apparent, the findings may well have a genetic basis and recurrence in future pregnancies is possible.

General Studies

In a newborn with one or more obvious major malformations or with multiple minor anomalies, imaging studies are often indicated to identify other anomalies. Whether or not significant other anomalies are identified, these studies will further describe the phenotype of the affected neonate. Detection of major anomalies involving the brain, heart, and kidneys is particularly important for diagnostic purposes, and it also may allow for more appropriate management and more accurate prognostication. Echocardiography is useful because congenital heart defects are among the most common major malformations with specific indications for genetic testing. Ultrasonography of the head and abdomen is useful to screen for major structural anomalies of the brain, kidneys, and liver. Head ultrasonography is a crude study for brain abnormalities, and if brain abnormalities are suspected, more definitive procedures such as magnetic resonance imaging are indicated. Newborns with skull abnormalities, short stature, or foreshortened long bones should have a skeletal survey to evaluate for skeletal dysplasias.

Ophthalmology evaluation also can be useful in diagnosing the neonate with congenital anomalies, especially if brain malformations or neurologic abnormalities are present. This evaluation also should be performed if small genitalia are present in a male infant (septo-optic dysplasia) or if features of the CHARGE syndrome are present.

The neonate with ambiguous genitalia requires a battery of tests, including chromosome analysis (see later) to determine genotypic sex, pelvic ultrasonography to identify internal genitalia, and endocrine testing (17-OH progesterone, testosterone, luteinizing hormone, follicle-stimulating hormone). It is best to defer assignment of sex until many of these tests have been performed and a urologist has evaluated the newborn. A psychologist can be very useful in helping the family deal with the uncertainty.

The value of the postmortem examination cannot be overemphasized. A thorough evaluation by an experienced pathologist can yield findings that would not be identified otherwise and that may lead to a definitive diagnosis and thus information about recurrence risk and possible prenatal testing in future pregnancies. The role of the clinician is to educate the family about the importance of such an evaluation.

Genetic Laboratory Studies

Table 29-7 shows typical cytogenetic, molecular, and biochemical tests performed on neonates with congenital anomalies.[19] Chromosome analysis, either by routine karyotype or CGH or chromosomal microarray analysis arrays, is indicated in all newborns with ambiguous genitalia, two or more major anomalies, multiple minor anomalies, or growth restriction in association with anomalies. Such studies should be performed even if a prenatal chromosome analysis had normal findings, because of improvements in resolution in identifying small deletions or amplifications. CGH and chromosomal microarray analysis are two relatively new techniques in molecular cytogenetics that allow for the detection of deletions and duplications too small to be seen in a high-resolution chromosome analysis. Like FISH, array analysis is able to detect small chromosomal imbalances, except that the newer generation arrays can simultaneously examine the entire genome. Depending on the study population, CGH or chromosomal microarray analysis is able to identify an additional 5% to 10% of cases with genomic imbalance compared with routine karyotyping.[13,34] However, CGH may not have a high level of specificity, and it also can identify deletions or amplifications known as *copy number variants* that may or may not be associated with the phenotype of the neonate.[45] Thus, care must be taken when interpreting the CGH array results. Parental samples are recommended to determine whether the copy number variant occurs de novo or is inherited from a normal parent and is unlikely to cause the anomaly in question.

Controversy exists over the use of microarray before examination of the karyotype because the clinical utility of the newer genomic tests has not been established. Nevertheless, if a karyotype result is normal for an infant with multiple anomalies, a microarray should strongly be considered as a follow-up test. FISH testing can be ordered if there is a high level of suspicion for a known microdeletion syndrome not detectable by routine cytogenetic analysis, such as velocardiofacial/DiGeorge syndrome or Williams syndrome, and a microarray analysis is not available. FISH has shown that a significant number of neonates with conotruncal heart defects have a 22q microdeletion, so this testing is indicated in all patients with truncus arteriosus, interrupted aortic arch, and tetralogy of Fallot.

TABLE 29–7 Genetic Diagnostic Tests Commonly Used in Newborn Medicine

Indication*	Condition	Approach
Hypotonia	Myotonic dystrophy	Targeted mutation analysis of trinucleotide repeat
	Spinal muscular atrophy	Deletion analysis of exon 7 in *SMN1* gene
	Prader-Willi syndrome	Methylation studies of chromosome 15
	Congenital disorders of glycosylation	Analysis of serum transferrin glycoforms
Multiple anomalies	CHARGE syndrome	Gene sequencing of *CHD7*
	Noonan syndrome	Sequencing of four genes in the Ras pathway: *PTPN11*, *KRAS*, *RAF1*, and *SOS1*
	Microdeletion syndromes (e.g., 1q41-q42 or 16p11-p12.1)	CGH array
Abnormal genitalia, isolated or with other anomalies	Camptomelic dysplasia	Gene sequencing of *SOX9*
	WAGR or Denys- Drash	Gene sequencing of *LIT1*
Ambiguous genitalia	CAH	17-OH progesterone
	Smith-Lemli-Opitz Syndrome	7-Dehyrocholesterol
	45,X/46,XY	Karyotype
Small infant or dwarfism	Achondroplasia, hypochondroplasia, thanatophoric dysplasia	Targeted sequencing of *FGFR3*
Pierre Robin sequence	Velocardiofacial/DiGeorge syndrome	FISH 22q11 deletion probe
	Stickler syndrome	Genetic sequencing of *COL11A1*, *COL11A2*, or *COL2A1*
Congenital heart disease		
Conotruncal defects	Velocardiofacial/DiGeorge syndrome	FISH 22q11 deletion probe
Supravalvular aortic stenosis	Williams syndrome	FISH for *ELN* gene deletion
Coarctation of aorta	Turner syndrome	Karyotype
Pulmonic stenosis	Noonan syndrome	Sequencing of four genes in the Ras pathway: *PTPN11*, *KRAS*, *RAF1*, and *SOS1*

*This list is not exhaustive, and the appropriate genetic test for all these indications is dependent on the phenotype of the neonate.

Adapted from Goodin K: Advances in genetic testing and applications in newborn medicine, *NeoReviews* 9:282, 2008; and Slavotnek AM: Novel microdeletion syndromes detected by chromosome microarrays, *Hum Genet* 124:1, 2008.

CAH, congenital adrenal hyperplasia

Once a syndrome or syndromes are suspected in the differential diagnosis, molecular genetic analysis of specific genes should be considered. Molecular gene-based testing has become a useful tool in diagnosing the newborn with congenital anomalies because the number of genes identified to cause malformation has increased. For example, in those infants with unexplained hypotonia and contractures, DNA testing may identify an expansion in the myotonic dystrophy gene or mutations in the spinal muscular atrophy gene. Fifty percent of infants with Pierre Robin sequence will have an identifiable genetic cause such as mutations in the collagen genes (*COL11A1*, *COL11A2* or *COL2A1*) causing the autosomal dominant Stickler syndrome, or deletion in 22q11, causing velocardiofacial/DiGeorge syndrome.[16]

The medical sequencing technology should be understood by the ordering clinician because some molecular tests examine the most frequent sequence variants and other methods sequence the entire coding regions of the causative gene. Thus, a targeted test could miss a true causative mutation in a particular patient. Further, sequence variants of unclear pathogenicity have been commonly identified across the genome so care should be taken when correlating a putative mutation with the phenotype.

Biochemical testing for many metabolic malformation syndromes is also possible. Metabolic conditions were traditionally thought of as not being associated with congenital anomalies, but this concept is changing. A definitive diagnosis of multiple malformation Smith-Lemli-Opitz syndrome can be made by obtaining a low serum cholesterol level and an elevated 7-dehydrocholesterol level. Congenital disorders of glycosylation, an autosomal recessive disorder with a wide variety of abnormalities, is diagnosed by serum transferrin glycoform analysis. Presumably, many other conditions with congenital anomalies will be found to have a biochemical basis, which will allow for more definitive diagnoses and appropriate management strategies (see Table 29-7).

GENETIC COUNSELING

Genetic counseling should be provided at some point to all parents of children with major malformations or multiple anomalies. Genetic counseling is a communication process during which families are informed about the abnormalities present in the affected individual, with medical and genetic knowledge discussed in practical language. It can be given by any health care professional, but it is most often provided by genetic counselors, who typically work with genetic physicians. Genetic counselors are individuals with master's degrees who have been specifically trained to understand genetic disorders and congenital anomalies and to help families with the psychological and emotional adaptation to having a family member with a serious and chronic problem. Medical or clinical geneticists are physicians who have received special training in genetic counseling and in the diagnosis and management of genetic disorders and birth defects.

Genetic counselors provide supportive counseling to families, assist families in coping with a lifelong condition, and serve as patient advocates. Genetic counseling for congenital anomalies should include a description of the abnormality, the natural history, associated abnormalities, and prognosis for the disorder. The etiology of the abnormality (if known), whether genetic or nongenetic, is explained in such a manner that the family can understand. The family also is given reassurance that the condition in the affected individual is not the fault of any individual, and information about recurrence risk is provided. Analysis of the pedigree can then identify family members who are at increased risk for being affected or having affected offspring. These relatives should also learn about the disorder, and receive an explanation of the reproductive options available for the condition, particularly the prenatal and preimplantation technologies, complications, and accuracy. Assistance should be offered in reaching a decision about prenatal or postnatal testing. Information about appropriate community services and family support organizations also is offered.[54]

EDUCATIONAL RESOURCES AND SUPPORT ORGANIZATIONS

With almost universal access to the Internet, the number of education resources for clinicians and families about genetic conditions has increased greatly, from clinical description to chromosomal and molecular databases.[6,18] The National Library of Medicine's National Center for Biotechnology Information (NCBI; www.ncbi.nlm.nih.gov/_) hosts several gene-specific websites that are particularly relevant for the neonatologist or perinatologist who is evaluating an infant with congenital anomalies. GeneTests provides a detailed description of many single-gene disorders and gives information about clinical genetic testing availability and interpretation, also providing current lists of resources for families (GeneTests; (www.ncbi.nlm.nih.gov/sites/GeneTests/fidb=GeneTests). An excellent reference for all single-gene conditions is the Online Mendelian Inheritance in Man (OMIM; www.ncbi.nlm.nih.gov/omim).[39]

Because most congenital anomalies and genetic disorders are relatively rare, usually occurring with a frequency of 1 in 1000 or less, family support organizations have been developed to help combat the isolation and grief felt by families who have or have had an affected child. These groups usually offer support and empathy and serve as a clearinghouse for information about the disorder and its management. Often they have a newsletter for members that describes helpful coping mechanisms and keeps families updated on relevant resources and research. Such organizations often have been started by and are usually staffed by parents of affected individuals or by affected individuals themselves. As a result, they vary greatly both in the format and content of what they offer and in the accuracy of the information they distribute. Organizations for more frequent disorders, such as Down syndrome, are usually large and professionally run; offer educational forums, such as an annual conference and lay literature; keep listings of resources locally and nationally; and may even offer grant funding for research on the disorder. Smaller organizations for less common conditions may serve primarily a social and support function. Because of this variability in the knowledge of support organizations and the resultant uncertainty concerning the accuracy of information provided, it is advisable for the physician to become familiar with an organization and its functions before referring a family.

The Genetic Alliance (www.geneticalliance.org/) provides information services for individuals and disease-specific organizations. The Alliance supplies contact information and data about the organizations. Another group, the National Organization for Rare Disorders (NORD; www.rarediseases.org/), functions as a clearinghouse for information on genetic disorders; it will send a summary of this information written for lay individuals for a small fee, will match families, and will make medical referrals, if appropriate. The March of Dimes (www.marchofdimes.com/) provides excellent lay information about specific genetic disorders.

SUMMARY

It is the role of the neonatologist to direct the evaluation of the newborn or stillborn with congenital anomalies. Diagnostic testing and evaluations, along with consultation of references and specialists in the field, such as medical geneticists and dysmorphologists, may be helpful. The goal is to identify the etiology to improve medical management and to provide accurate information on prognosis and recurrence risk that can be shared with the family.

SECTION V

Provisions for Neonatal Care

CHAPTER 30

Physical Environment

PART 1

The Thermal Environment

Gunnar Sedin

Protecting infants against excessive heat loss improves their chances for survival, reduces their need to perform heat-producing metabolic work, and eliminates the problems associated with rewarming of cold infants. Although incubators can be traced back to ancient Egypt, where they were used for hatching of chicken eggs, incubators intended for human infant care did not exist until the late 1870s. The incubator was part of Professor Trainer's technology for enhancing the survival of prematurely born babies. The history of incubators is the history of neonatal medicine, which includes the bizarre but critically important use of incubators to display human infants in sideshow exhibits (see Chapter 1).

During intrauterine life, heat production by the fetus results in a fetal temperature that is about 0.5°C higher than the maternal temperature.[11] After birth, the newborn infant is exposed to air and surfaces facing the infant, which have a much lower temperature than that previously experienced in utero. The skin at birth is covered with amniotic fluid, causing heat loss through evaporation in an environment with a low vapor pressure.[23,36] As a result, the body temperature of the infant decreases, and the rate of this reduction is influenced by the temperature of the environmental air in the delivery room and airflow. This gives rise to thermogenic responses that increase basal heat production,[11,14] and the skin circulation may decrease to lower the heat losses.[58]

Heat balance in newborn infants depends on the heat transfer between the infant and the environment.[*] This transfer is related to the temperature and humidity of the environmental air (the vapor pressure), the flow velocity of that air, the temperature of the surfaces facing the infant (ceiling, walls of room or incubator or bedding material), and the temperature of the surfaces in contact with the infant.[†]

After birth, the immediate interventions required to avoid body cooling are to wipe off the amniotic fluid from the skin surface to lower the loss of heat through evaporation, and to cover the infant with a warm, dry towel or blanket, or both, to lessen the exposure of the infant's skin to the environment.[23,26] The infant born at term or moderately preterm can be covered with a blanket and then placed on the mother's chest,[6,7,67] but extremely preterm infants usually need other measures to maintain their body temperature, usually placement in an incubator or under a radiant heater[*] and, if necessary, mechanical ventilation with warm and humidified gas.[43,44,48,60,63]

ROUTES OF HEAT EXCHANGE

Heat exchange between the infant and its environment occurs through the skin and through the respiratory tract. It has previously been difficult to estimate the heat exchange between the infant and the environment. The introduction of new techniques to measure the evaporation rate from the skin[†] and from the respiratory tract[32,39-42,47,50] has permitted the heat loss through evaporation to be determined.[26] It is also possible to calculate the heat loss through other modes of heat exchange, such as radiation, convection, and conduction; to determine the heat loss per unit surface area and from the total body surface area[47]; and to take into consideration the proportions of surface area participating in the different modes of heat exchange.[23,24,26,37] In addition, the modes of heat exchange between the infant's respiratory tract and the environment can be measured.

WATER AND HEAT EXCHANGE BETWEEN THE INFANT'S BODY SURFACE AND THE ENVIRONMENT

Heat exchange through evaporation, radiation, convection, and conduction can be calculated with knowledge of the transepidermal water loss, the temperature of the infant's skin (T_{skin}), the temperature of the walls facing the infant (T_{wall}), the temperature of the ambient air (T_{amb}), the temperature of the material on which the infant is placed (T_{bed}), and characteristics of the material in the infant's environment, using the equations given in the following sections.[23,24]

Determination of Water Loss from the Skin

In the absence of forced convection, and if the effect of thermal diffusion is disregarded, the process of water exchange through a stationary water-permeable surface can be expressed in terms of the vapor pressure gradient immediately adjacent to the surface.[21,35]

The evaporation rate (ER; grams/meter^2/hour) from the infant's skin can thus be determined by a method based on calculation of the water vapor pressure in the layer of air immediately adjacent to the vapor pressure and the distance from the evaporating surface.[35] In this zone, the relationship between the vapor pressure and the distance from the evaporating surface is linear.[35] If the gradient in this layer is known, the amount of water evaporated per unit time (or transepidermal water loss [TEWL]), can be calculated[35] according to the following equation:

$$\mathrm{TEWL} = 0.92 \times \mathrm{ER}_{(a,b,c)} + 1.37$$

where $\mathrm{ER}_{(a,b,c)}$ is the arithmetic mean of ER measured from the chest, an interscapular area, and a buttock.[21,46,47,50]

The gradient method (Evaporimeter, ServoMed AB, 51121 Varberg, Sweden), allows quick measurements of free evaporation without disturbing the infant.[21,35] TEWL is a mean value of cutaneous water loss and can be calculated according to the equations below.

CALCULATIONS OF HEAT EXCHANGE BETWEEN THE INFANT AND THE ENVIRONMENT

Exchange at the Surface

Heat exchange through evaporation (H_{evap}), can be calculated if TEWL is known[21,35,46,47,50] according to the following equation:

$$H_{evap} = k_1 \times \mathrm{TEWL}\ (3.6 \times 10^3)^{-1}\ (\mathrm{W/m^2})$$

where k_1 is the latent heat of evaporation (2.4×10^3 J/g), and 3.6×10^3 is the correction factor for time (seconds).

Heat exchange through radiation (H_{rad}) can be determined if the mean temperature of the skin (T_1;Kelvin [K]) and the mean temperature of the surrounding walls (T_2;K) are known:

$$H_{rad} = S_0 \times e_1 \times e_2 \times (T^4{}_1 - T^4{}_2)\ (\mathrm{W/m^2})$$

where S_0 is the Stefan-Boltzman constant (5.7×10^{-8} W/m^{2}K^4), e_1 is the emissivity of the skin, and e_2 is the emissivity of the surrounding walls (0.97).

Heat exchange through convection (H_{conv}) can be calculated if the mean temperature of the skin (T_1;K) and the mean temperature of the ambient air (T_3;K) are known:

$$H_{conv} = K_2\ (T_1 - T_3)\ (\mathrm{W/m^2})$$

where K_2 is the convection coefficient (2.7 W/m^2/K). The coefficient for convection given previously and used in many studies referred to in this chapter has usually been determined in measurements on adult human skin.[37] A convection coefficient suggested as being more valid for newborn infants[66] can alternatively be used, and H_{conv} will then be 48% higher.

Heat exchange through conduction (H_{cond}) can be determined if the temperature of the skin (T_{skin};K) and the temperature of the bed (T_{bed};K) are known:

$$H_{cond} = k_0\ (T_{skin} - T_{bed})\ (\mathrm{W/m^2})$$

In this equation, k_0 is a conductive heat transfer coefficient. With the thermal conductivity characteristics of most regular mattresses, the heat loss through conduction is very low.

The extent of heat exchange between the body surface area and the environment thus depends on the type of heat exchange, on the position and geometry of the body,[26,47] and on the magnitude and frequency of body movements. Because different modes of heat exchange are unequally influenced by changes in the body position, the relative contribution of different modes of heat exchange might vary with time. Heat exchange is often presented per unit area of body surface exposed to the ambient air or facing the walls of the incubator.

HEAT EXCHANGE BETWEEN THE INFANT'S RESPIRATORY TRACT AND THE ENVIRONMENT

Expired air is usually more humid than inspired air and has a higher water vapor pressure. This implies that evaporative loss of water and heat takes place from the respiratory tract. Convective heat transfer, usually of low degree, also occurs in the respiratory tract. In research, these two processes are considered together.[29] In the newborn, heat can also be gained through the respiratory tract if the infant inspires very warm air with a high humidity. Because of the alternating displacement of air during the respiratory cycle, convective and evaporative heat transfer in the respiratory tract is complex. When ambient air, which is cooler than the body, passes along the mucosa during inspiration, it gains heat by convection and gains water vapor by evaporation from the mucosa. On reaching the alveoli, the air is at thermal equilibrium with the central body temperature and is saturated with water. During expiration, the expired air may become a little cooler than the body temperature before it leaves the infant.

DETERMINATION OF WATER LOSS FROM THE AIRWAY

Respiratory water loss (RWL) is usually included in measurements of total insensible water loss when these are performed with ventilated chambers, but it can be estimated separately.[28,63] Hey and Katz[28] and Sulyok and colleagues[63] found that the RWL was higher at a low ambient humidity than at a high humidity. In other studies of RWL, an open flow-through system has been used with a mass spectrometer to measure the gas concentrations. Ambient air is then sucked through a specially constructed Teflon funnel attached to the infant (or the lamb), so that all expired air is collected without inclusion of evaporation from the surrounding skin.[39] This system provides data on RWL, oxygen consumption, and carbon dioxide production.[39-44,57]

Calculation of Heat Exchange between the Infant's Respiratory Tract and the Environment

The exchange of heat through convection in the respiratory tract, $H_{conv\text{-}r}$, is calculated from the air volume ventilated per unit time (V = ventilation volume) and from the temperature difference between expired and inspired air ($T_E - T_I$) according to the following relationship:

$$H_{conv\text{-}r} = V \times \rho \times c\ (T_E - T_I)\ m^{-1}\ (W/kg)$$

where ρ is the density of the air (1 g = 0.880 l), c is the specific heat ($1\ J \times g^{-1} \times {}^{\circ}C^{-1}$), and m is the body weight (in kilograms).[47]

Because of the alternating inspiratory warming and expiratory cooling of the air, the convective heat exchange in the respiratory tract depends mainly on the temperature of the inspired air. In human infants nursed in incubators, there is a small difference between the temperatures of the inspired and of the expired air, and convective losses are small.

Evaporative heat exchange from the airway ($H_{evap\text{-}r}$) depends on the difference in water content between the expired and the inspired air. This is the RWL.[39-44]

As the formation of water vapor in the respiratory tract requires thermal energy, the amount of heat exchange by evaporation per unit time is expressed by the following equation:

$$H_{evap\text{-}r} = k_1 \times RWL\ (3.6 \times 10^3)^{-1}\ (W/kg)$$

where k_1 is the latent heat of evaporation of water (2.4×10^3 J/g) and $(3.6 \times 10^3)^{-1}$ is the correction factor for time.

HEAT EXCHANGE IN INCUBATORS, UNDER RADIANT HEATERS, AND IN HEATED BEDS

When it was realized that a good thermal environment increases the chances of survival of newborn infants, attempts were made to provide them with a warm environment. Budin in 1900 found a higher survival rate in infants whose temperature had never been below 32°C.[12] Later studies have shown that the ambient temperature influences the survival rate and oxygen consumption in newborn infants[14,27,28] and that a body temperature of about 37°C is appropriate for newborn infants at rest.[42] At a high ambient temperature, term infants start to sweat, and if they are fed cold glucose through a gastric tube, sweating is inhibited.[62]

Incubators

In a convectively heated incubator, the warm air supplied should be directed so that both the air temperature of the incubator and the incubator walls are kept warm. If the airflow velocity is lower than 0.1 m/second, the convective heat transfer will depend on the gradient between the skin and the air temperature, and the vapor pressure gradient close to the skin surface will be maintained, avoiding an increased evaporative rate due to increased airflow velocity.[29,37,47,66] An evaluation of environmental and climate control in incubators[57] has shown that the airflow velocities and capacity for humidification vary markedly between different types of incubators. Also, the wall temperatures vary considerably between different incubators,[57] and it is therefore necessary to determine the airflow velocities, humidity, and wall temperatures carefully before calculating heat exchange. With airflows higher than 0.2 m/second, there will be a forced convection.

Radiant Heaters

A radiant warmer placed over an open bed platform provides good accessibility and visibility for the care of the newborn infant and has therefore become widely used in neonatal intensive care. Infants nursed under a radiant heater gain heat, but they may also have extensive heat losses through evaporation and convection and also, from some surfaces, through radiation,[8,31-33,59,60] making it difficult to estimate the relative contributions of different modes of heat exchange. Because of the free movements of air above the infant's body surface, both evaporative and convective heat loss may increase as a result of a high air velocity.

Heated Beds

In the 1989, Sarman and coworkers found that infants weighing 1000 g or more can be kept warm by placing them on a heated water-filled mattress early after birth.[45] By covering most parts of the body except the face, direct heat exchange between the infant's skin and the environment through other modes can be almost eliminated in a large proportion of the body surface.

Preterm and term infants can maintain a normal body temperature during skin-to-skin care if they are placed lying naked except for a diaper on the mother's or father's chest and are covered with the mother's clothing or a blanket.[6,7,67] Only parts of the head are exposed to the environmental air[6,7,67] and will exchange heat with the environment.

WATER AND HEAT EXCHANGE BETWEEN THE SKIN AND THE ENVIRONMENT

In a series of studies, water evaporation from the skin surface of infants nursed in incubators has been determined by use of the gradient method (the ServoMed Evaporimeter), and TEWL[21,22,25,46] and heat exchange have been calculated.[23,24,26] In these studies, the body temperature has been maintained at 36° to 37°C except when the effect of warming has been investigated, and the ambient humidity has been kept at 50% except when the effects of different humidities have been analyzed. Evaporative heat loss is usually insensible but might become sensible when term infants are nursed in a warm environment and start to sweat.[62] Some infants born at term and nursed in a warm environment do not begin to sweat,[62] and if they do, the sweating is preceded by an increase in skin blood flow. In preterm infants, the sweat glands are nonfunctional.[28]

Heat Exchange during the First Hours after Birth

Immediately after birth, when the infant's skin is covered with amniotic fluid, there is an enormous evaporative heat loss from the skin surface. This evaporative heat loss decreases gradually during the first hours, whether the infant is nursed in the delivery room or in an incubator (Fig. 30-1, top two

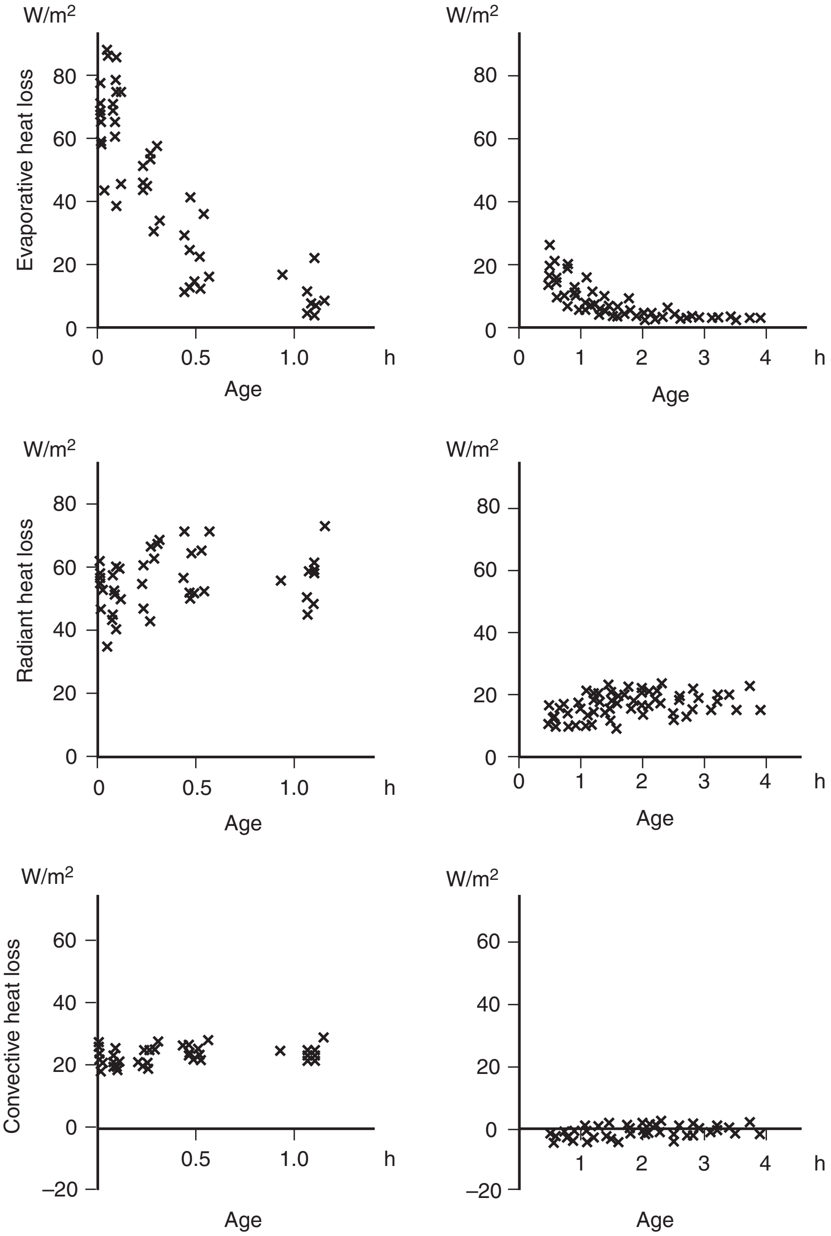

Figure 30–1. Heat exchange between the skin of term infants and the environment immediately after birth and during the first 1 to 4 hours postnatally. The infants were not washed or wiped. Data presented in the left-hand scatter diagrams are based on measurements in infants initially placed at the delivery bed or at the mother's chest and later in a cot. After the measurements made 1 and 5 minutes after birth, the infants were covered with a towel between the measurements. Data in the right-hand diagrams are based on measurements in infants who were covered with a towel after birth and until they were placed in an incubator. *(From Hammarlund K, et al: Transepidermal water loss in newborn infants: V. Evaporation from the skin and heat exchange during the first hours of life,* Acta Paediatr Scand *69:385, 1980.)*

diagrams).[23] Heat loss through radiation is high if the infant's skin is facing the walls of the delivery room and is much lower if it is facing the inner walls of the incubator (see Fig. 30-1, middle diagrams).[23] The heat loss through convection is lower than that through radiation but is much higher when the infant is nursed in room air (see Fig. 30-1, lower left diagram) than when nursed in the incubator (see Fig. 30-1, lower right diagram).

Transepidermal Water Loss during the First 4 Postnatal Weeks

The transepidermal water loss (TEWL) from the skin surface of the newborn infant depends primarily on the gestational age at birth,[22] but it is also influenced by the postnatal age.[25] The transepidermal water loss in newborn infants is also lower in infants who are small for gestational age[46] than in those who are appropriate for gestational age.[22,25,46] There is an exponential relationship between TEWL and gestational age in infants who are appropriate for gestational age when measurements are made during the first day after birth.[22] This relationship prevails during the first 4 weeks after birth, even though the difference in TEWL between the most preterm infants and term infants who are appropriate for gestational age gradually diminishes with increasing age. The evaporation rate and TEWL both depend on the ambient relative humidity or ambient vapor pressure.[22,46] This relationship appears to be valid for all gestational ages and is also valid for all postnatal ages studied.[21,22,25,46,49]

Heat Exchange during the First Day after Birth

The evaporative heat exchange is directly proportional to the amount of water that evaporates from the infant's skin and shows the same type of relationship to gestational age as TEWL.[24,46] When infants are nursed in an ambient humidity of 50%, the evaporative heat exchange may reach 50 W/m^2 of the body surface area in the most preterm infants,[24] whereas in term infants, it is close to 5 W/m^2 (Fig. 30-2). The high evaporative heat loss in very preterm infants makes it necessary to have a very high ambient temperature in the incubator to maintain a normal body temperature of 36° to 37°C. The servocontrol system of the incubator that controls the skin temperature also regulates the temperature of the air, which leads to changes in the temperature of the incubator walls and thereby influences the heat exchange through convection and radiation.

Most preterm infants can even gain heat through these modes of heat exchange. The preterm infants were being nursed in an incubator with a relative humidity of 50%, at a higher ambient vapor pressure than the more mature infants need.[25,46] This means that the heat exchange between the very preterm infants and their environment could have been even greater if comparisons had been made at equal ambient vapor pressures instead of at equal ambient humidities.

In studies of the effects of different ambient humidities, it was found that infants born at a gestational age of less than 28 weeks need a T_{amb} of about 40°C to maintain a normal body temperature at an ambient humidity of 20%, whereas term infants need a T_{amb} of about 34°C at this ambient humidity (Fig. 30-3). Nursing very preterm infants at a higher ambient humidity means that a lower ambient temperature can be sufficient to maintain a normal body temperature.[24]

Heat Exchange at Different Ambient Humidities

Evaporative heat exchange between the skin of very preterm infants and the environment is highest at a low humidity,[24] and lower at higher ambient humidity. In fact, heat exchange through evaporation in the most preterm infants is twice as high at 20% as at 60% ambient humidity. Other modes of heat exchange are all influenced by the ambient humidity (Fig. 30-4). The sum of the different modes of heat exchange, in the different gestational age groups, is almost the same, but the total heat loss cannot be calculated in this way because the proportions of the body surface area exchanging heat in different ways are not exactly known.

Heat Exchange during the First Weeks after Birth

The high evaporative losses of heat from the infant's skin that are seen in the most preterm infants during the first days after birth will gradually decrease with increasing postnatal age

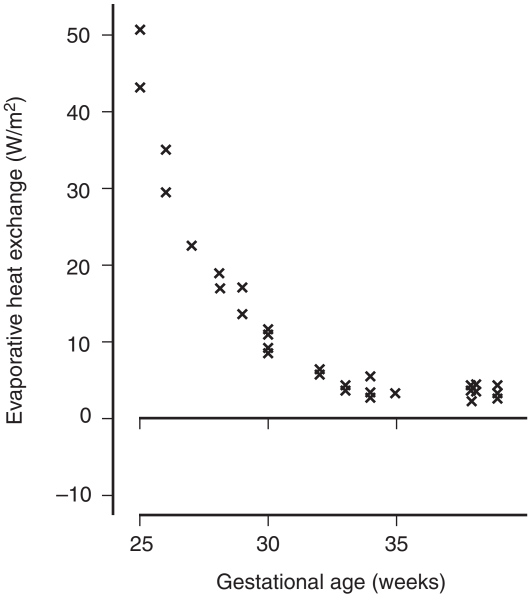

Figure 30–2. Heat exchange through evaporation at an ambient humidity of 50% in relationship to gestational age. Measurements were made during the first 24 hours after birth in preterm infants and during the first 30 hours in term infants. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants: VI. Heat exchange with the environment in relation to gestational age,* Acta Paediatr Scand *71:191, 1982.)*

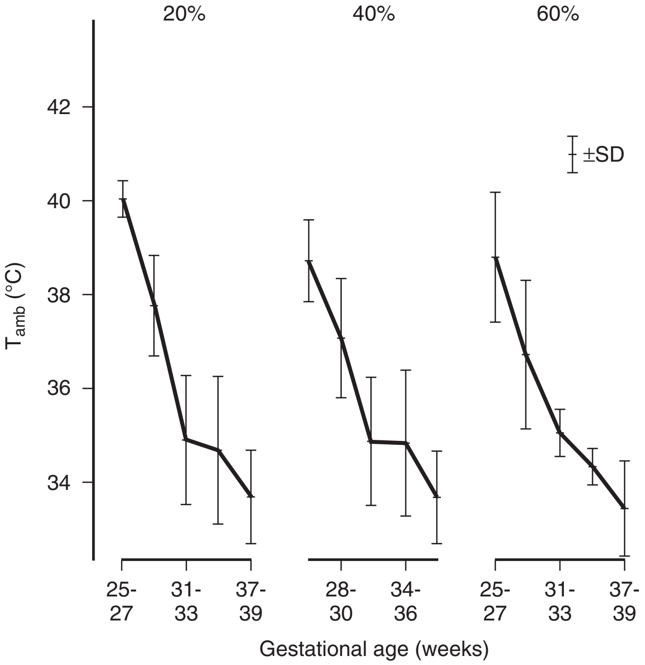

Figure 30–3. The relationship between gestational age and the ambient temperature (T_{amb}) needed to maintain a normal body temperature at three different humidities of 20%, 40%, and 60%. Measurements were made during the first 24 hours after birth in preterm infants and during the first 30 hours in term infants. SD, standard deviation. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants: VI. Heat exchange with the environment in relation to gestational age,* Acta Paediatr Scand *71:191, 1982.)*

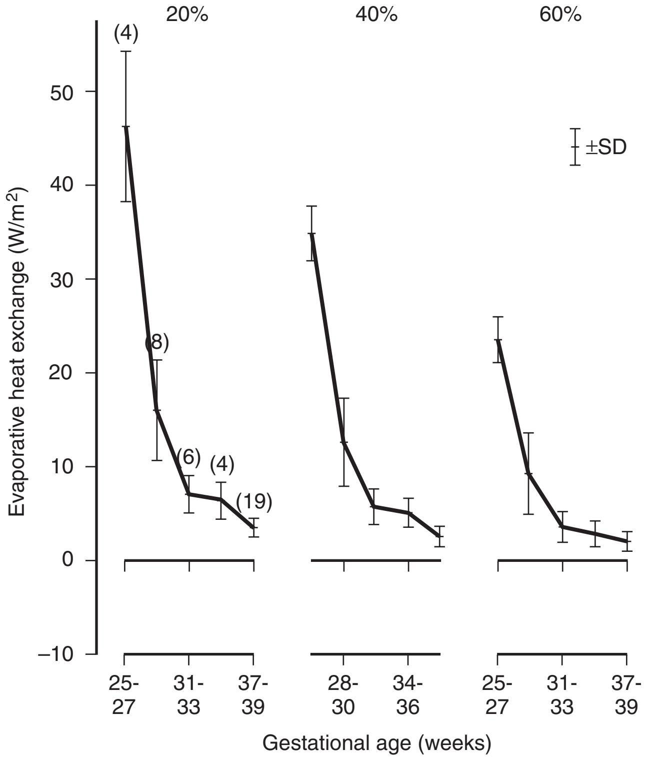

Figure 30–4. Heat exchange through evaporation in relation to gestational age at relative ambient humidities of 20%, 40% and 60%. SD, standard deviation. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants: VI. Heat exchange with the environment in relation to gestational age. Acta Paediatr Scand 71:191, 1982.)*

(Fig. 30-5).[26] Heat loss through radiation is low early after birth in the most preterm infants born at 25 to 27 weeks of gestation. Heat loss from radiation will, however, be the most important mode of heat exchange after the first postnatal week. In infants born at a gestational age of 28 weeks or later, heat exchange through radiation is the most important mode of heat exchange from birth, and it gradually increases with age. Heat exchange through convection is low in infants nursed in incubators. Initially, there is a gain of heat through convection in the most preterm infants early after birth.

During the first weeks after birth, the relative magnitude of the different modes of heat exchange markedly depend on the ambient humidity (Fig. 30-6). In infants born at 25 to 27 weeks of gestation and nursed in a dry environment, evaporative heat exchange will be the most important mode of heat exchange for more than 10 days after birth. At an ambient humidity of 60%, this mode of exchange is the highest only during the first 5 days. Thereafter, radiation is the most important mode of heat loss.[26]

The total heat exchange between the infant's skin and the environment can be calculated if the body surface area of the infant and the fractions of this area that participate in the different modes of heat exchange are known.[26,28] This is difficult with available methods, especially if estimations are to be made over a longer period of time.[26] The total heat exchange is basically dependent on the metabolic rate.

Heat Exchange between the Infant's Skin and the Environment during Care under Radiant Heaters

Several investigators have considered that a lower vapor pressure in the ambient air[9] and more convective air currents under the radiant heater[8] cause an increase in evaporative water loss and heat exchange. Later determinations of the evaporation rate from the skin of term, moderately preterm, and very preterm infants nursed in incubators with 50% ambient humidity and under a radiant heater have shown that the evaporation rate from the skin surface of term infants is significantly higher under a radiant heater than in an incubator.[33] In moderately preterm infants born at 30 to 34 weeks of gestation, the evaporation rate from the skin is significantly higher at an environmental humidity of 30% than at 50%, and in very preterm infants with a gestational age of less than 30 weeks, the evaporation rate is higher under a radiant heater than in an incubator at an environmental humidity of 50%.

A transparent heat shield positioned over the infant can lower the heat exchange (occurring through both convection and evaporation) between the infant and its environment, decrease convective air currents, and increase humidification[8] and diminish the water loss.[9,16,17] It has been suggested that a bed platform, which can be used with a radiant heater or with a hood, might make it easier to adapt to the mode of care that such an infant needs.[20] Modern incubators have been designed to incorporate these elements and optimize thermal regulation.

Ambient Humidity Influences the Rate of Skin Barrier Maturation in Extremely Preterm Infants

To investigate whether the level of relative humidity in which preterm infants are nursed might influence their postnatal skin maturation,[2] TEWL was determined in 20 preterm infants (gestational age, 23 to 27 weeks) nursed at postnatal ages of 0, 3, 7, 14, and 28 days.[3] At a postnatal age of 7 days, the infants were randomized to care at either 50% or 75% relative humidity. It was found that TEWL decreased at a slower rate in infants nursed at the higher relative humidity of 75% than at 50%. Thus, at a postnatal age of 28 days, TEWL was about twice as high in infants nursed at 75% relative humidity (22 ± 2 g/m²/hour) than in those nursed at 50% relative humidity (13 ± 1 g/ m²/hour; $P < .001$). The results indicate that the level of relative humidity influences skin barrier development, with more rapid barrier formation in infants nursed at a lower relative humidity. The findings have an impact for promoting skin barrier integrity in extremely preterm infants (Figs. 30-7 to 30-9).[3] A table further documents that there are no significant differences between the group of infants nursed at a relative humidity of 75% and those nursed at a relative humidity of 50% (Table 30-1).

Heat Exchange between the Infant's Skin and the Environment during Phototherapy

Phototherapy has been reported to increase insensible water loss in newborn infants.[8,9]

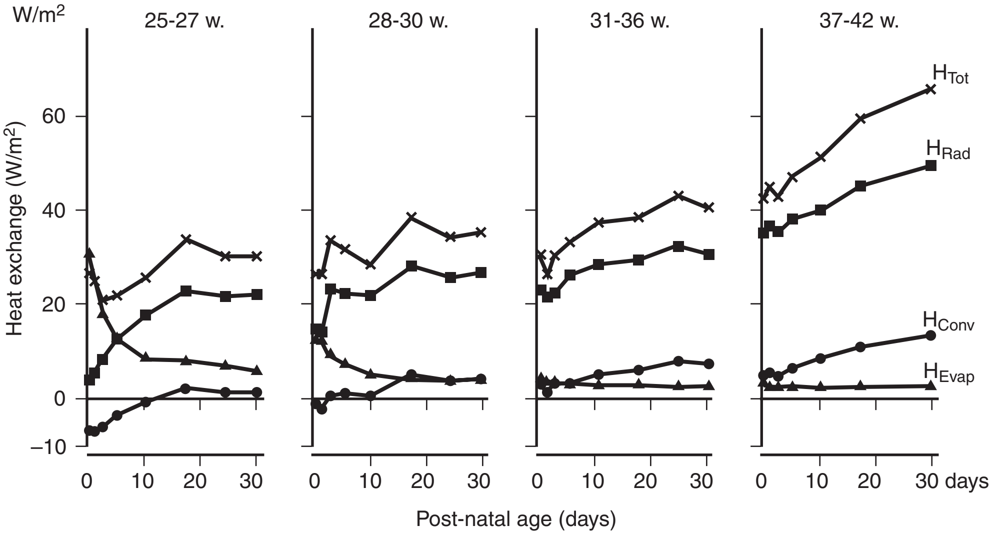

Figure 30–5. Heat exchange between the infant and the environment per square meter body surface area in relation to postnatal age in different gestational age groups at an ambient humidity of 50%. (*From Hammarlund K, et al: Heat loss from the skin of preterm and full term newborn infants during the first weeks after birth,* Biol Neonate *50:1, 1986.)*

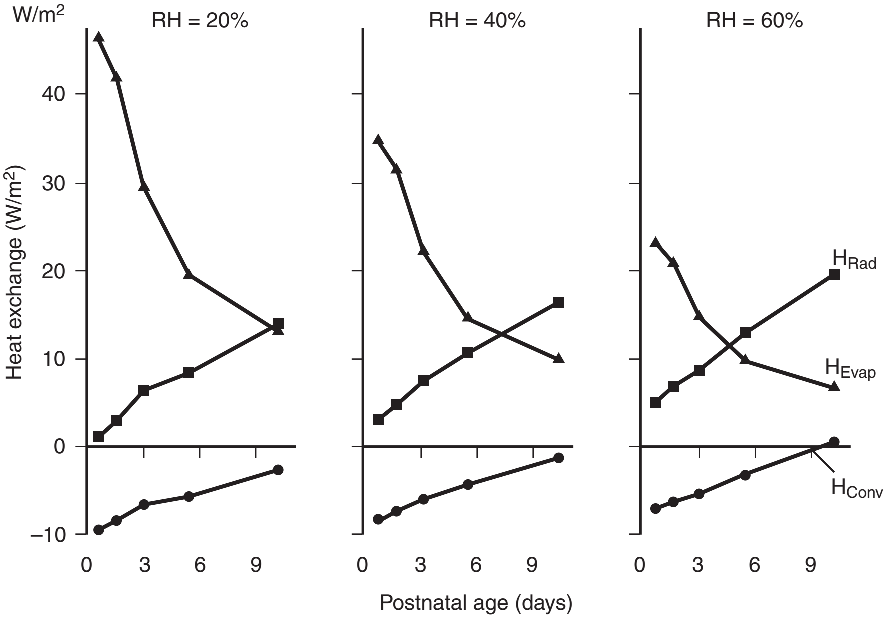

Figure 30–6. Heat exchange between the infant and the environment in relation to postnatal age at relative ambient humidities (RH) of 20%, 40% and 60% in infants born at 25 to 27 weeks of gestation. (*From Hammarlund K, et al: Heat loss from the skin of preterm and full term newborn infants during the first weeks after birth,* Biol Neonate *50:1, 1986.)*

This loss of water and heat might be caused by altered barrier properties in the skin or by increased RWL. However, other studies have indicated that in thermally stable term and preterm infants,[31] there is no increase in the evaporation rate from the skin surface during phototherapy.

Heat Exchange between the Infant's Skin and the Environment during Care on a Heated Bed

An infant on a heated bed gains heat through conduction. Some losses of water and heat from the airway will take place, depending on the vapor pressure of the room air. Sarman and colleagues showed that infants weighing 1000 g or less could be kept warm when nursed on a heated water-filled mattress.[45] In a 2-week trial with infants whose birthweight was between 1300 and 1500 g, Gray and Flenady found that weight gain was lower and body temperature higher in those who were cot-nursed with warming than in those who were nursed in an incubator.[19]

Heat Exchange between the Infant's Skin and the Environment during Skin-to-Skin Care

After the introduction of skin-to-skin care for newborn infants,[67] Bauer and coworkers showed that preterm infants younger than 1 week and with a birthweight of less than

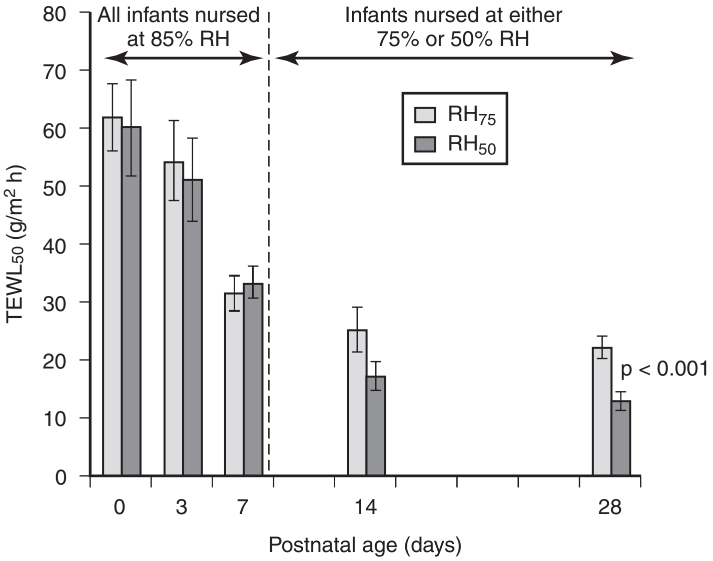

Figure 30–7. Transepidermal water loss corrected to a relative humidity of 50% ($TEWL_{50}$) in infants nursed either at 75% relative humidity (RH_{75}) or 50% relative humidity (RH_{50}) from postnatal age (PNA) of 7 to 28 days. During first 7 days, all infants were nursed at RH of 85%, and no differences in $TEWL_{50}$ are noted. After adjustment of RH at PNA of 7 days, skin barrier function improved more rapidly in infants nursed at lower RH. (*From Agren, et al: Ambient humidity influences the rate of skin barrier maturation in extremely preterm infants,* J Pediatr *148:613, 2006.)*

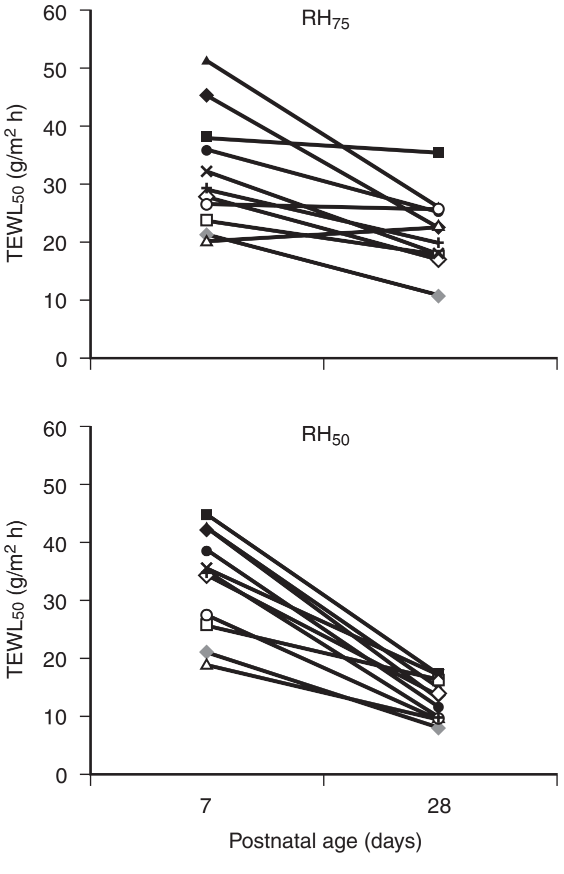

Figure 30–8. Changes in transepidermal water loss corrected to a relative humidity of 50% ($TEWL_{50}$) from postnatal age (PNA) of 7 to 28 days in individual infants nursed at 75% relative humidity (RH_{75}) (*upper panel*) and at 50% relative humidity (RH_{50}) (*lower panel*). Decrease in $TEWL_{50}$ was consistently more pronounced in infants at lower RH. (*From Agren, et al: Ambient humidity influences the rate of skin barrier maturation in extremely preterm infants,* J Pediatr *148:613, 2006.)*

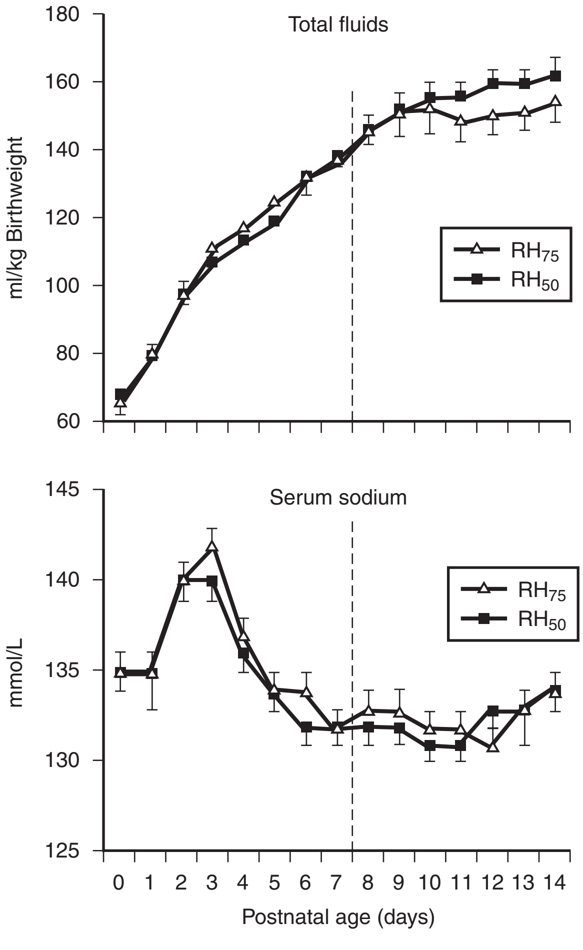

Figure 30–9. Daily total fluid intake (*upper panel*) and serum sodium levels (*lower panel*) at postnatal age (PNA) of 0 to 14 days in infants nursed at 85% RH from days 0 to 7, then at 75% relative humidity (RH_{75}) or at 50% relative humidity (RH_{50}) from 7 days PNA (*indicated by dashed lines*). There are no statistically significant differences between study groups. (*From Agren, et al: Ambient humidity influences the rate of skin barrier maturation in extremely preterm infants,* J Pediatr *148:613, 2006.)*

TABLE 30–1 Background Data on Infants Nursed at a Relative Humidity of 75% (RH_{75}) and of 50% (RH_{50})

		STUDY GROUPS*		
		RH_{75} (n = 11)	RH_{50} (n = 11)	*P* Value
Gestational age (wk)		24.9 (23-27)	25.0 (23-26)	0.79
Sex (female/male)		5/6	3/8	
Birthweight (g)		731 (395-995)	748 (530-995)	0.58
Cesarean delivery (*n*)		5	3

CPAP, continuous positive airway pressure; PDA, patent ductus arteriosus; PNA, postnatal age; BW, birthweight.

1500 g were not exposed to cold stress during 60 minutes of skin-to-skin care in stable preterm infants.[6] Similarly, preterm infants born at 28 to 30 weeks of gestation and studied during the first and second week after birth increased their body temperature during 1 hour of skin-to-skin contact with no significant change in oxygen consumption.[7] More immature infants, born at 25 to 27 weeks of gestation, showed no increase in oxygen consumption but a decrease in rectal temperature during the same duration of skin-to-skin contact during the first week after birth.

During the second postnatal week, body temperature did not change in infants born at 25 to 27 weeks of gestation during skin-to-skin care.[7] It has been suggested that infants born at 25 to 27 weeks of gestation might have a very high evaporative heat loss during the first week after birth, causing cold stress.[22,26]

Keeping the Very Preterm Infant Warm Early after Birth

Newborn infants are at risk for losing heat soon after birth. It is therefore of great importance to wipe off amniotic fluid from the skin surface, remove wet linen, and wrap the infant in prewarmed blankets or, alternatively, place the infant skin-to-skin on the mother's chest to use her body as a heat source.[67]

When an infant is placed in an environment where the temperature and humidity are low, the evaporative heat and water exchange will be high and air movements in the environment may further increase the loss of heat through evaporation, conduction, convection, and radiation (Fig. 30-10).[23,24] It is of utmost importance to keep the infant warm. Dressing the infant in thin clothing after drying is helpful to maintain temperature.[30]

WATER AND HEAT EXCHANGE BETWEEN THE RESPIRATORY TRACT AND ENVIRONMENT

Water and heat loss from the respiratory tract takes place with each expiration. Using indirect methods, it has been shown that RWL depends on the humidity of the inspired air, with lower losses occurring at a high humidity.[28,60] The RWL (mg/kg per minute) can be determined using a flow-through system with a mass spectrometer for measurements of gas concentrations.[39-44,47,50,57] In an environment with an ambient humidity of 50%, the evaporative heat loss from the airway will be moderate[39]; that is, in term infants whose weight is appropriate for gestational age, the insensible water loss from the respiratory tract (IWL_R) and that from the skin (IWL_S) will be of equal magnitude.[39] The evaporative heat loss from the respiratory tract ($H_{evap\text{-}r}$) and the evaporative heat loss ($H_{evap\text{-}s}$) from the skin will also be of equal magnitude under these conditions.

The evaporative loss of water and heat from the airway depends on the ambient humidity both in lambs and infants,[39]

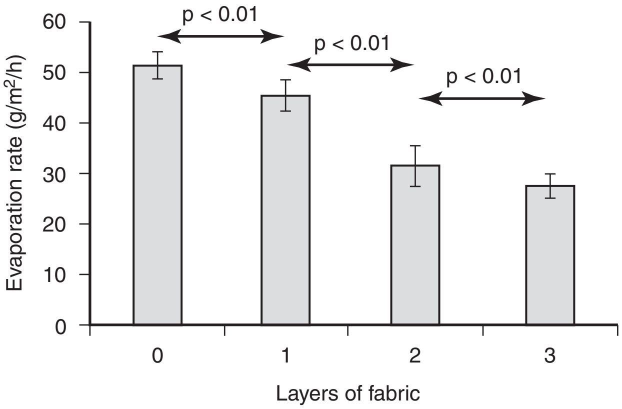

Figure 30–10. Evaporation rate (ER; g/m^2/hr) measured from the semipermeable membrane alone and from the membrane covered by layer(s) of cotton fabric. ER is reduced for each layer added. *(From Kjallstrom et al: How to keep the preterm infant warm; Water flux through thin clothing, personal communication.)*

with lower losses at a high humidity than at a low humidity. Whereas IWL$_S$ decreased from 9 to 2 g/kg per 24 hours in term infants when the ambient humidity was increased from 20% to 80%, the corresponding change in IWL$_R$ was much smaller, that is, from 9 to 5 g/kg per 24 hours.[39] In infants placed in a calorimeter, Sulyok and associates[63] found that the respiratory heat loss was between 0.07 and 0.22 W/kg, or 3% to 10% of the total heat production from metabolism and about 40% of the insensible heat loss. In term infants, RWL and $H_{evap\text{-}r}$ may increase during activity by up to 140% of the values at rest.[40]

In Table 30-2, data are presented on IWL$_S$ and IWL$_R$ showing that moderate heat stress in both lambs and infants can increase their RWL and $H_{evap\text{-}r}$ without increasing their oxygen consumption and CO_2 production.[41-43] Exposure to radiant heat can alter the RWL in a lamb while leaving the oxygen consumption and CO_2 production unchanged. RWL is directly proportional to the rate of breathing,[41-43] which means that lambs and infants will lose more water and heat when they have a high rate of breathing (Fig. 30-11). Oxygen consumption will increase if heat stress induces bodily movements with higher levels of activity (see Table 30-2).[40]

TABLE 30–2 Effect of Activity Level on Insensible Water Loss and Oxygen Consumption

Activity Level	IWL$_S$	IWL$_R$	IWL$_T$	$\dot{v}o_2$
0	6	6	12	8
1	—	8	—	9
2	—	9	—	10
3	—	10	—	11
4	—	12	—	12
5	7	16	23	13

Insensible water loss from the skin (IWL$_S$) and from the respiratory tract (IWL$_R$) and their sum (IWL$_T$) in g/kg/24 h, and oxygen consumption ($\dot{v}o_2$; L/kg/24 h), in term, appropriate-for-gestational-age infants at different levels of activity.

From Riesenfeld T, et al: Respiratory water loss in relation to activity in full term infants on their first day after birth, *Acta Paediatr Scand* 76:889, 1987.

Respiratory Water and Evaporative Heat Loss in Relation to Gestational Age

The infants were usually asleep during the measurements.[44] RWL was found to be highest in the most preterm infants and lower in more mature infants studied in incubators with 50% ambient relative humidity and an ambient temperature that allowed the infant to maintain a normal and stable body temperature. RWL per breath (mg/kg) was almost the same at all gestational ages, and the higher RWL values found in the most preterm infants compared with the more mature infants was thus due to the higher rate of breathing.[44]

Respiratory Water and Evaporative Heat Exchange during Phototherapy

When term and preterm infants were exposed to phototherapy in the absence of heat stress, there were no significant changes in RWL, oxygen consumption, CO_2 production, or rate of breathing (Table 30-3).[32]

Respiratory Water and Heat Exchange during Mechanical Ventilation

In clinical neonatal care with a warm and humid environment or with warm and humidified gas supplied from a respirator, heat exchange through evaporation and convection

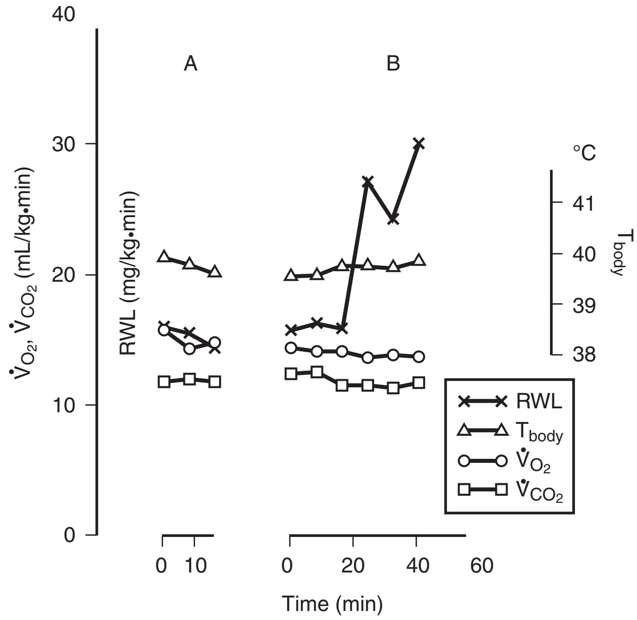

Figure 30–11. Respiratory water loss (RWL), body temperature (T_{body}), oxygen consumption ($\dot{v}o_2$) and CO_2 production ($\dot{v}co_2$) in a 6-day-old lamb before (A) and during (B) heat stress. *(From Riesenfeld T, et al: Influence of radiant heat stress on respiratory water loss in newborn lambs,* Biol Neonate *53:290, 1988.)*

TABLE 30–3 Effects of Phototherapy on Respiratory Values in Neonates

Phototherapy Status	*N*	RWL (mg/kg/min)	$\dot{V}O_2$ (mL/kg/min)	$\dot{V}CO_2$ (mL/kg/min)	RR (breaths/min)
Before	11	4.4 ± 0.7	5.9 ± 0.9	4.0 ± 0.7	48 ± 7
12 min	11	4.4 ± 0.6	5.9 ± 1.0	3.9 ± 0.6	—
24 min	10	4.1 ± 0.8	5.5 ± 1.1	3.8 ± 0.7	—
36 min	9	4.2 ± 1.0	5.4 ± 1.0	3.6 ± 0.6	—

between the respiratory tract and the environment is low.[39,63] Infants who inspire cold air with a low water vapor pressure will have high evaporative loss from the respiratory tract and will also lose heat through convection. These losses may become of clinical significance, for instance, during transport in a cold climate.[48]

NEUTRAL THERMAL ENVIRONMENT

The concept of an optimum thermal environment for newborn infants evolved during the 1960s.[1] This idealized setting, called the neutral thermal environment, is characterized as the range of environmental temperature within which the metabolic rate is at a minimum and within which temperature regulation is achieved by nonevaporative physical processes alone (Fig. 30-12). There is no reason to believe that the normal temperature of infants is different from that of adults. An infant's internal temperature within the range of 36.5° to 37.5°C (with a diurnal variation of ± 0.5°C) is probably normal. Because body temperature is a measure of only the balance between heat production and net heat loss, a normal body temperature should not be confused with a "normal" metabolic rate.[1]

A cold-stressed infant depends primarily on mechanisms that cause chemical thermogenesis (see Fig. 30-10). When an infant is stimulated by cold, norepinephrine[61] is released,

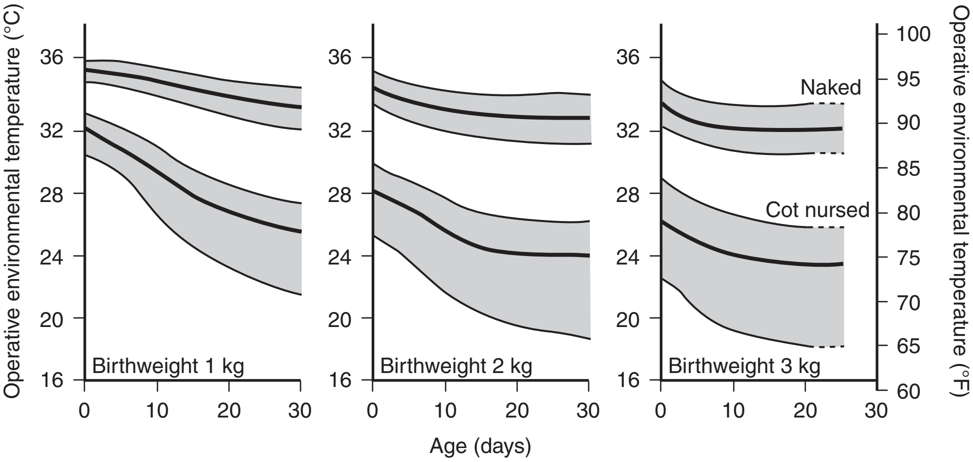

Figure 30–12. The usual ranges of environmental temperatures needed to provide warmth for infants weighing 1 to 3 kg at birth in draft-free, uniform-temperature surroundings at 50% relative humidity. *Upper curves* represent naked infants, and *lower curves* represent swaddled, "cot-nursed" babies. *Thick lines* represent usual "optimal" temperature, and *shaded areas* are the range within which to maintain normal temperature without increasing heat production or evaporative water loss by more than 25%. The operative environmental temperature inside a single-walled incubator is less than the internal air temperature recorded by the thermometer; the effective environmental temperature provided by the incubator can, however, be estimated by subtracting 1°C from the air temperature for each 7°C the incubator air temperature exceeds room temperature. *(From Hey EN: The care of babies in incubators. In Gairdner D, et al, editors:* Recent advances in paediatrics, *4th ed. London, 1971, Churchill Livingstone.)*

inducing lipolysis in brown fat stores principally found in the interscapular, paraspinal, and perirenal areas. Because of the protein thermogenin, brown fat can decouple oxidative phosphorylation and break down fats to produce heat, without the inhibitory feedback loop of adenosine triphosphate production. Triglycerides in the fat are broken down to fatty acids and glycerol. The fatty acids enter thermogenic metabolic paths that end in the common pool of metabolic acids. Brown fat is turned on in response to skin thermoreceptors before a decrease in core temperature, and shivering is initiated by a decrease in core temperature.

Glycolysis also may be stimulated during severe stress when epinephrine released from the adrenals activates glycogen stores, which may result in transient hyperglycemia.[38] Lowered blood sugars in cold-stressed infants also have been reported,[13] possibly caused by inhibition of glycolysis, by lipolysis, or by exhaustion of glycogen stores.

SUMMARY

The exchange of heat between the infant's skin and the environment is influenced by the insulation provided by the skin, the permeability of the skin, and environmental factors such as the ambient temperature and humidity, airflow velocity, and the temperature and characteristics of the incubator surfaces facing the infant.

Evaporative heat loss from the skin is the major component of heat exchange in the most preterm infants early after birth, and these infants gain heat through convection and, in a very dry environment, possibly also through radiation when they are nursed in an incubator. As water loss from the skin surface of most preterm infants decreases with postnatal age, heat loss through evaporation from the skin also decreases. Their need for a high ambient temperature also diminishes, and with the lower temperature of the incubator walls, the heat loss through radiation then increases, and the heat gain by convection is changed to a low loss of heat during the first weeks after birth.

Infants nursed under a radiant heater gain heat through radiation, and as a result of the low ambient humidity, evaporative loss of water and heat may be high in very preterm infants. In term infants nursed in incubators with an ambient humidity of 50%, the evaporative water and heat loss from the respiratory tract and from the skin are of about the same magnitude. Respiratory water and evaporative heat loss is low in term infants.

Loss of heat through convection greatly depends on how the infant is protected from high air velocities by arrangements made under the radiant heater, and also on the magnitude of movements in the nursery.

The respiratory evaporative water loss and heat loss per breath are of about the same magnitude in calm preterm and term infants. In preterm infants, the evaporative heat losses from the skin are much more important than such heat losses from the respiratory tract. The evaporative heat loss from the airway might be considered important only in infants with high motor activity or with tachypnea, especially if they are nursed in a very dry environment. Mechanical ventilation with dry and cold air also results in high loss of heat from the respiratory tract through evaporation and convection.

PRACTICAL CONSIDERATIONS

The body temperature of preterm infants can drop precipitously after delivery. Reports of hypothermia in infants of all birthweights on admission to neonatal units have come from all over the world. Recent reports that showed that hypothermia on admission to neonatal units is an independent risk factor for mortality in preterm babies have refocused attention on the need for meticulous thermal care immediately after birth and during resuscitation. Their data lend weight to the view that conventional approaches to thermal care of the very preterm infants and those with low birthweight are outmoded. Bathing newborns shortly after birth increases the risk for hypothermia despite the use of warm water and skin-to-skin care for thermal protection of the newborn.[10] During the first 12 hours of life, the temperature in infants with extremely low birthweight may also decrease during procedures such as umbilical line insertion, intubation, obtaining chest radiographs, manipulating intravenous lines, repositioning, suctioning, and even taking vital signs. Precautions should be undertaken to prevent heat loss during these procedures.

How to Keep a Baby Warm

THE DELIVERY ROOM

In the delivery room, a large proportion of heat loss is caused by evaporation. The skin should be dried with warm towels, and evaporative losses should be limited by using plastic bags or other swaddling materials to insulate the skin from the dry room air.[51-53] Polyethylene occlusive skin wrapping is an alternative to decrease heat loss after delivery.[64] Even with the most careful drying of the newborn, it is almost impossible to dry the hair completely. To keep the head warm, it may be necessary to use caps or hooded blankets. For very preterm infants, polyethylene caps are comparable with polyethylene occlusive skin wrapping to prevent heat loss after delivery.[63b] Furthermore, the use of heated and humidified air just after birth appears to reduce postnatal hypothermia.[63a]

To keep the resuscitation of a newborn from interfering with thermal protection, the child should be placed on a preheated radiant warmer at full heater power at the start of the resuscitation. If the child requires more than 10 minutes of resuscitation, the temperature probe should be secured to the infant to control the skin temperature.[65]

The control of heat loss must continue during the transfer of an infant from the delivery room to another care area. Even within the delivery room, the infant should remain swaddled for display to the parents. If the mother desires skin-to-skin contact with her infant, they should be swaddled together under warm blankets (see Chapter 33). In transferring a sick baby to the neonatal intensive care unit, the caretaker should be sure that the transport incubator is prewarmed and that the hot air in the transport incubator is not allowed to escape by opening the incubator widely to place the baby inside.

THE NURSERY

Swaddling may be an ancient practice, but it is not archaic. In fact, it is a simple and effective method for keeping larger babies warm who do not need to be unclothed for procedures or observation. Infants who are swaddled can be maintained in cooler ambient environments and can tolerate wider variations in environmental temperatures than infants who are naked. Nonetheless, swaddling alone does not keep small preterm infants warm at room temperature, and even term babies require additional heat if they must be exposed for observation. The alternatives when more heat is needed can be reduced to three common choices:

1. Warm the room.
2. Place the infant in a warm, enclosed incubator.
3. Place the infant under an open radiant heater.

The Warm Room

Heating a room to 36° or 37°C to keep some small and sick infants warm may distress personnel working in the nursery. These conditions also may be unfavorable for larger and healthier infants in the same area. For long-term care, heating and humidifying nurseries to appropriate temperatures is probably the least desirable method for limiting heat losses from infants, although in short-term situations such as in radiology departments, operating rooms, and treatment rooms, this method of protection can be the most applicable and effective. Ambulances used for transportation between institutions should always be warmed before initiating the transfer. Wrapping a small swaddled infant in a heated water pad controlled to a temperature of 40°C or less and adjusted with continuous measurement of skin and core temperatures can be used for brief periods when warming the room or using a radiant heater is impractical.

Convectively Heated Incubators

Convectively heated incubators create a microclimate in which to care for an individual infant. They consist of a chamber whose walls are a single or double layer of plastic, in which an infant is placed on an insulating mattress. The plastic walls of the chamber can be opened or have portholes to provide hand access to the enclosed infant. All convectively heated incubators use fans to force filtered room air at various rates of flow over relatively large heaters and, in some devices, pans that can be filled with water to increase environmental humidity. The heating of incubator air can be controlled by a feedback loop mechanism referenced to the temperature within the chamber itself or elsewhere in the air stream that heats the chamber.

Overhead (Open) Radiantly Heated Beds

The use of overhead radiant heaters to keep infants warm has become popular because they provide unimpeded access to infants receiving intensive care. Overhead radiant heaters are usually high-energy heat sources that require the use of skin servocontrol to ensure that infants do not become overheated when under their influence. The only exception to this requirement is when radiant heaters are used to protect infants for short periods immediately after birth.

Because of the known risk for causing hyperthermia when using a radiant heater, manufacturers have been improving the alarm logic in heater control designs. There also are provisions for silencing alarms. Failure to reactivate silenced alarms may expose infants under radiant heaters to a subsequent risk for severe hyperthermia; thus, the safe use of a radiant heater requires an informed awareness of the specific way that the alarms operate when the heater is used.

When comparing oxygen consumption of premature babies in incubators and radiant warmers, controlled to provide the same abdominal skin temperature, there is a slightly higher metabolic requirement in the radiant warmers. Infants nursed in the radiant warmers may also have cooler foot temperatures, which may reflect differences in the relationship between abdominal skin temperature and mean skin temperature; that is, infants nursed in radiant warmers may have a lower mean skin temperature than those nursed in incubators if they both have the same abdominal skin temperature. A skin temperature of 36.5° ± 0.5°C rather than 36.0° ± 0.5°C may be needed to ensure a minimal metabolic rate in a radiant warmer. Particular infants may have a thermoneutral skin temperature at or beyond either of these extremes in either device. Errors in skin temperature measurement are more important in infants in radiant warmers because the thermal gradients between the infant's skin and various parts of the environment are much larger with a radiant warmer.

The Cold Infant

Simply stated, infants get cold when heat losses exceed heat production. Defining a specific temperature beneath which an infant can be declared to be cold is less simple. An infant with homeothermic responses may become hypermetabolic and acidotic if the body temperature cools from 37° to 36°C. Because such an infant is responding to cooling, it would be justifiable to believe that this infant with a body temperature of 36°C is cold. Assume that the same infant is now cooled further to 35°C and then rewarmed to 36°C. The infant at this same body temperature of 36°C is no longer hypermetabolic. Is the 36°C body temperature in this warming infant still to be considered cold? Because of such dilemmas, it is better to define hypothermia using dynamic rather than static criteria. In general, an infant is cold only if it senses the heat loss as a stress and responds with a metabolic increase in heat production. As the normal rise in temperature that occurs because of the specific dynamic action of food is not considered to be fever, the normal drop in body temperature that occurs when an infant falls asleep should not be considered hypothermia. The use of the word *cold* implies that the condition is potentially or actually harmful. When cold is used as a sign of infant condition, further study is required to determine whether the sign reflects a true symptom from the infant's perspective. One infant with a body temperature of 35.5°C may be hyperactive, vasoconstricted, tachypneic, tachycardic, hypermetabolic, and acidotic. Another with the same temperature may be sleeping and content. It is difficult to believe that similar meanings are contained when *cold* is applied as a description of their conditions.

Hypothermia may be a subtle sign of sepsis. An infant may not become hypermetabolic and febrile when septic because of reduced responsiveness to bacterial pyrogens. Profound sepsis that produces shock and vasodilation can increase heat loss while suppressing an infant's normal homeothermic reactions. Such an infant, although previously able to maintain a warm body temperature in a cool environment, may get colder in the same environment. Although the lower limit of normal temperature is frequently cited as being 36°C, individual variation beyond this value does exist.

Debates about the comparative virtues of rapid versus slow rewarming procedures notwithstanding, there is no convincing argument available to certify any method as better than another. Because rewarming some infants may induce apnea, an infant should be constantly observed and the environment carefully analyzed and controlled during the rewarming process. As a first step in rewarming, a heat-gaining environment should be produced to eliminate any further significant heat losses from the infant. In a radiant warmer, set the skin temperature to 36.5°C to produce rapid rewarming and to 1°C above the core temperature to produce slow rewarming. The existence of a heat-gaining environment can be certified only if the infant begins to get warmer. In an incubator, simply warming the air temperature to a level that is higher than the infant's temperature is inadequate. The actual environmental temperature in a convectively heated, single-walled incubator may be 1° to 2°C less than the measured air temperature.

Evaporative losses should be minimized by raising the incubator's humidity. For small infants in radiant warmers, raise the humidity around the infant or otherwise reduce the evaporative heat loss. Radiant losses in incubators should be minimized by protecting the incubator walls from excessive cooling or by use of an inner heat shield. If evaporative and radiant losses are minimized, the absolute air temperature becomes more meaningful.

The Infant Who Is Too Hot

Most neonatal thermoregulatory studies have focused on the effects, prevention, and amelioration of hypothermia. Hyperthermia has been noted primarily as a sign of hypermetabolism when an infant is septic or otherwise stimulated. It is probably beneficial to cool an infant who has become febrile because of exposure to an overheated environment. Whether it is good to cool infants who are febrile because they are septic, or otherwise stressed by internal conditions, is less clear, although it is usually attempted.

An infant with a body temperature higher than 37.5°C is often considered to be abnormally warm. To determine whether the elevated temperature is caused by an increase in heat production, which might occur if the infant is septic, or by a decrease in heat loss, some simple presumptive clinical measures can be made.

A physiologically competent infant responds to overheating from a hot environment by incorporating heat-losing mechanisms. The infant's skin vessels dilate, the infant may appear flushed, the hands and feet are suffused and warm, and the infant assumes a spread-eagle posture. Evaporative losses increase and, although it is uncommonly observed in premature infants, active sweating may be noted in the term infant. If the heat stress is severe, the infant may become hyperactive and irritable. During rapid warming, the skin of the infant is warmer than the infant's core temperature.

An infant who is febrile because of an increase in endogenous heat production reflects a state of stress. The febrile infant, during the phase of rising temperature, perceives the environment to be too cold. The infant is vasoconstricted, and compared with the skin on the trunk, the extremities appear pale and blue and feel cold. Unlike the gradients expected in overheated infants, the core temperature of the hypermetabolic infant is warmer than the skin temperature. In the overheated infant, the rectal temperature may be the same as the skin temperature.

Hypothermia as Neuroprotection against Neonatal Encephalopathy

(See Chapter 40, Part 4)

Hypothermia for neuroprotection as "rescue" therapy in neonatal encephalopathy after acute perinatal asphyxia has been shown to be safe and feasible in case series and randomized controlled trials.[4,5,15,18,55] In these studies, the target core temperatures achieved during cooling have been reduced to a depth of 34° to 35°C, duration of cooling has been extended up to 72 hours, and cooling has been achieved by either selective head cooling or whole-body cooling. Although follow up studies are still in progress, the results of the first multicenter trials are very encouraging. Hypothermia either alone or in conjunction with medication offers some hope as a therapy for neonatal asphyxia in term infants.

PART 2

The Sensory Environment of the Intensive Care Nursery

Robert D. White

Sensory development begins early in fetal life in an environment that is quite different from that of the neonatal intensive care unit (NICU). In an uncomplicated pregnancy, the fetus spends the full gestational period in a warm, dark, contained womb that is the source of extensive kinesthetic, auditory, and gustatory stimuli. After a normal birth, in most civilizations throughout history, the infant then spends several more months (the "fourth trimester") in close proximity to its mother, who continues the familiar stimuli from in utero and is the primary source of a gradual increment of new visual, auditory, olfactory, gustatory, and tactile stimuli.

The NICU unavoidably and dramatically alters this normal progression of sensory development. Not only are familiar stimuli replaced by unfamiliar ones, but they also are apprehended by the infant in a much different fashion—auditory stimuli arrive through an air medium rather than the liquid and solid medium of the amniotic fluid and uterus, tactile stimuli are frequently uncomfortable or painful, visual stimuli may have little relationship with a circadian rhythm, and so forth.

In addition, the sensory environment is important not only for the infants in an NICU but also for their parents and caregivers, and many times the needs of these three constituencies are in conflict with one another. In this chapter part, we review what is known about how the sensory environment of the NICU affects infants, and in Part 3, we describe how this knowledge, along with the needs of parents and caregivers, informs the physical design and operation of the NICU.

OVERVIEW

In the last 3 months of gestation, the fetal brain increases in mass by 400%,[11] and to a similar extent in complexity and organization. This is equal to the 400% growth that occurs from term delivery to adulthood, yet we have generally assumed that nearly all learning occurs after birth. In reality, though, a substantial amount of learning occurs during the third trimester, whether a baby is in or ex utero.

Sensory development occurs in a highly programmed, sequential fashion. Normal development of the senses depends largely on biologically expected, orderly sensory input; when this input is absent, disordered, or replaced by unexpected stimuli, the result can be abnormal and sometimes permanently impaired development of one or more sensory modalities.[14] What follows is a brief overview of how each sensory domain develops in utero as well as how the stimuli differ for infants in the NICU.

TOUCH AND MOVEMENT

Touch is the most difficult to describe as a unique sensory modality because elements of movement, pain, temperature sensitivity, and proprioception are all entwined with the tactile aspect in the mature individual. Touch is the first sense to develop in the fetus, with reflexive movement to a touch stimulus seen as early as 8 weeks. Tactile and kinesthetic stimuli are presented to the infant throughout pregnancy, and the fetus itself actively initiates such stimulation from a very early stage.

In the NICU, elements of both overstimulation and understimulation can be found, along with randomness and atypical, biologically unexpected stimuli. Taking kinesthetic stimulation as an example, this occurs in utero with the infant in a contained environment, with a liquid-solid interface, and with little influence from gravity. Movements tend to be gentle, often prolonged (as when the mother is walking), and occur with a definite circadian rhythm. In the NICU, however, an infant may spend an extended period of time lying on a flat mattress, interrupted at irregular and unpredictable intervals to be moved suddenly, unnaturally, and sometimes painfully. The NICU infant is constantly "touched" by monitoring devices, indwelling devices, and surfaces that have a much different consistency and impact on the skin than would be experienced in utero. Skin injury is very common in the most premature infants, which may have an additional effect on the sensory experience in the NICU.

TASTE AND SMELL

The senses of taste and smell become functional by 24 to 28 weeks' postconceptional age[22] and, soon after, reach a level of competence comparable to that of the term infant. Maternal dietary flavors are transmitted to the amniotic fluid and recognized as both flavors and odors by the term newborn, especially in breast milk.[15,18]

In the NICU, infants are exposed to a multitude of odors and tastes, most unfamiliar and many of them noxious.[1] Sometimes, these odors or tastes are associated with other noxious stimuli, and this interaction may affect the infant's response.[9] As with each of the other senses, it seems likely that prolonged skin-to-skin contact with the baby's mother would mitigate many of these differences between the in utero and NICU environments.

AUDITORY

The fetus responds to sound by the end of the second trimester,[2] and extensive development of the auditory system continues in the third trimester of fetal life. The in utero environment transmits sounds to the fetus through a liquid medium (the amniotic fluid) and, to some extent, through a solid medium as the infant approaches term and remains in more extended contact with the uterus. This environment attenuates sound, especially high-frequency auditory impulses. The sounds experienced by the fetus are primarily those of the mother—both of voice and bodily functions, and it is clear that by term birth, an infant is able to distinguish its mother's voice from those of other women,[6] but not that of its father.[7]

In the NICU, a cacophony of sounds arrives at the infant's ear at all hours, transmitted through an air medium that does not attenuate any frequencies. A consistent voice is rarely present, and often, human voices that are meant to be soothing precede and continue through unpleasant stimuli.

VISION

Visual input is not expected or needed until after term. Nevertheless, the visual cortex is in an active stage of development in the third trimester, under the control of endogenous stimuli that occur primarily during sleep cycles, and can be disrupted by analgesia, sedation, and sleep deprivation.[10]

CAREGIVER CONSIDERATIONS

There is a large body of literature on the effect of the sensory environment on the health and performance of adult workers. Even so, NICU caregivers often work under much less than optimal conditions, partly because hospitals have not historically given importance to the needs of caregivers, and partly because caregivers have been willing to sacrifice their needs to those of the infants for whom they were providing care.

Staff benefit from music, pleasant odors, and visual input in the workplace.[21] They appreciate some control over the environment and benefit from access to nature, especially daylight.[13] They also appreciate the opportunity to collaborate and socialize with their colleagues throughout the workday. Often, these needs are in conflict with those of the infants they care for. Good design can attenuate many of these conflicts, primarily by identifying gathering spaces for caregivers when they are not providing direct patient care.

CIRCADIAN BIOLOGY

Circadian rhythmicity is not one of the human senses, yet it is profoundly affected by the sensory environment and operates quite differently in the fetus than during the rest of life. In this respect, it may be a useful model for all the senses to illustrate how complex the relationship can be between the environment of the NICU, the infant, and its adult caregivers.

In utero, the fetus has a well-developed circadian rhythm by the end of the second trimester,[23] probably influenced by multiple maternal stimuli, including physical (movement, body temperature) and hormonal (transplacental melatonin, cortisol) *zeitgebers* (timekeepers). After birth, a diurnal rhythm is not well established in preterm infants even when they are in an NICU with cycled lighting, although this rhythm is established more quickly after discharge than in a control group treated in continuous dim lighting.[20] This is true even though the neural mechanisms to respond to a circadian light stimulus are intact by early in the third trimester.[12]

In exploring this phenomenon, one is struck by the absence in the NICU of the circadian stimuli that would be available to the fetus. Body temperature is rigidly servocontrolled, touch and kinesthetic stimuli are as likely to occur in the middle of the night as during the day, and access to maternal rhythms of melatonin and cortisol, present in breast milk, is prevented by administration of breast milk without regard for the time it was expressed, or by the use of artificial formula. Even skin-to-skin contact with the mother for several hours a day may not be sufficient to impart circadian information to the preterm infant.

Caregivers are faced with a quite different set of challenges. Most night-shift workers are nocturnal while working, but diurnal on their days off, leading to stress and sleep deprivation.[17] Although even moderate levels of light at night can suppress melatonin-induced sleepiness and improve alertness while reducing the normal night-time temperature decline,[24] attempts to keep the infant's environment dark may make supplemental lighting difficult to provide for caregivers. In addition, with evidence that night-shift workers are at increased risk for cancer[19] and that melatonin is beneficial in reducing tumor growth,[8] it is impossible to know at present what the ideal lighting environment is for night-shift workers, at least with respect to providing them an optimal work environment while causing the least harm.

SUMMARY

Unlike any other hospital patients, the preterm infant is going through a complex and vital stage of brain development in an environment that is far different from the expected norm. Simply attempting to mimic the in utero environment may not be beneficial, though; for example, a continuous dimly lit environment is not better than one with cycled lighting,[3,20] nor has exposing an infant to a tape recording of the maternal heart beat or voice been shown to provide benefit. On the other hand, extended skin-to-skin contact with the mother does more closely replicate the in utero stimuli a fetus would receive and has been shown to provide benefit.[4,5,16] The needs of caregivers create an additional layer of complexity when deciding the proper design and operation of an NICU in order to meet the sensory needs of all the occupants; strategies to address these concerns as well as many others are outlined in the following section.

PART 3

Design Considerations

Robert D. White and Michele C. Walsh

When the neonatal intensive care unit (NICU) is appreciated as a place where crucial brain growth and development occur over a period of weeks or months, it becomes apparent that the sensory environment has comparable importance to the provision of direct medical care. This is even more evident when one realizes that the physical environment can affect the physical and mental health and performance of the caregivers as well as parental involvement and satisfaction. Thus, proper design should provide the best technological and environmental support possible to all three constituencies—infants, families, and caregivers. This goal is difficult to achieve, not only because of space and financial limitations common to almost all construction projects, but also because some of these needs are in conflict with one another, as illustrated briefly in the previous discussion on circadian biology.

Certain basic standards for NICU design have been defined with these scientific and practical considerations in mind.[1,2,10] In this part, we review some of these standards (Box 30-1) and add practical suggestions for those who are considering alterations in the physical environment of their NICU.

ADJACENCIES

In an ideal setting, the NICU is located in close proximity to the high-risk delivery rooms—in some NICUs, close enough to use a pass-through window. In hospitals with large maternity services or in children's hospitals, however, the NICU may be on a separate floor or in a different building. In this case, a stabilization area must be provided within or adjacent to the high-risk delivery area where the infant can be stabilized before transfer to the NICU. Transfer should occur in a neonatal transport device with appropriate monitoring and respiratory support, proceed through nonpublic areas as much as possible, and use dedicated or controlled-access elevators.

BOX 30–1 Key Factors in Designing the Intensive Care Nursery

LOCATION
- Close proximity or controlled access to delivery and transport areas
- Controlled access and egress for patient and staff safety

SPACE ALLOCATION
- Minimum of 120 square feet per bed space, excluding sinks and aisles (150 square feet minimum for single patient rooms)
- Adequate and easily accessible storage (30 square feet per bed) for supplies and equipment

ACCESS
- At least 4-foot aisles in multibed rooms
- At least 8-foot corridors outside private rooms

PRIVACY
- Minimum of 8 feet between beds, with provisions for family and speech privacy

HEADWALL
- Twenty simultaneously accessible electrical outlets, divided between normal and emergency power circuits
- Three each of compressed air, oxygen, and vacuum outlets, all simultaneously accessible
- Data transmission port

HAND HYGIENE
- Large sinks with hands-free controls in each patient care room, and within 20 feet of every bed
- Sinks designed to accommodate children and persons in wheelchairs
- Appropriate provision for soap, towel dispensers, and receptacles for trash, recyclables, and biohazardous waste

SURFACES
- Floors[11]—easily cleanable, durable, glare free, and cushioned in patient care areas
- Walls—easily cleanable and durable; attractive visual accents and sound-absorbent materials can be used where they can be protected from damage
- Ceilings—washable, highly sound-absorbent acoustical tile wherever feasible

LIGHTING[12]
- Ambient lighting levels adjustable through a range of 10 to 600 lux
- No direct ambient lighting in patient care areas
- Light sources with suitable spectrum to permit accurate color rendering[4]
- Procedure lighting capable of providing at least 2000 lux at the bed surface, and adjustable in both location and intensity
- Daylighting for adult work areas, with appropriate shading and insulation

ACOUSTICS[8]
- Noise control measures to maintain the combination of background and operation sound below a mean level of 45 dB[9]

HEATING, VENTILATION, AND AIR CONDITIONING
- Ambient temperature of 22° to 26°C (72° to 78°F)
- Relative humidity of 30% to 60%
- Minimum of six air exchanges per hour with appropriate filtering; two changes should be with outside air
- Exhaust vents situated to minimize drafts near patient beds, and appropriately sized and constructed to minimize noise from airflow

FAMILY SUPPORT
- Adequate and welcoming directional and informational signage
- Lounge, refreshments, restrooms, storage, library, telephones
- Overnight rooms—at least one per five patient beds
- Consultation/grieving room
- Lactation area (if sufficient privacy is not available at the bedside)
- Dedicated area at the bedside for infant care, work, and rest

STAFF SUPPORT
- Lockers, lounge, restrooms, on-call rooms
- Adequate and comfortable charting/work area at each bedside
- Clerical/work areas away from, but easily accessible to, each bedside
- Office/desk space for all disciplines that routinely provide care

SUSTAINABLE DESIGN
- Use of materials that are free of substances known to be teratogenic, mutagenic, carcinogenic, or otherwise harmful to human health[7]
- Designs and materials that reduce consumption of energy, cleaning fluids, and nonrenewable resources[5]

Adjacencies to other support services in the hospital, including operating rooms, imaging, laboratory, and pharmacy, should be carefully considered, as should the traffic patterns for families to reach the NICU and the areas they may need to use for eating, sleeping, personal needs, and interacting with other families. While making access convenient for families, good design also minimizes the traffic of non-NICU visitors or staff for both safety and aesthetic reasons.

SINGLE-FAMILY ROOMS VERSUS MULTIPLE-PATIENT ROOMS

Private rooms have now become the standard for new construction in all inpatient areas in the hospital except for the NICU,[2] where the benefits and downsides of this concept are still debated. Many of these factors are summarized in Table 30-4. For some hospitals with limited space available, this is not an option because single-family room design requires at least 600

TABLE 30–4 Benefits of Single-Family and Multiple-Patient Rooms

Feature	Single-Family Room	Multiple-Patient Room
Privacy	Maximal	Easily compromised, but can be provided to some degree
Light and sound	Individualized	Generally targeted to most acutely ill infant
Parental role	Easily supported	Must be actively facilitated
Staff needs—communication	Must be accomplished by electronic means as well as with a central station	Visualization of and collaboration with other team members is generally easier
Infection control	Reduced risk of cross-contamination by staff	More ability to monitor family's adherence to infection control measures
Patient safety	Increased reliance on technological means to know when an infant needs attention	Permits some degree of direct visualization of the patient area at all times
Cost	Construction costs higher, and may require more staffing in some cases	In theory, may have higher infection rates and impaired neurodevelopment due to environmental factors

and preferably 800 gross square feet per bed (total available floor space divided by the number of beds) when the relatively fixed needs for support space are considered as well. Even for hospitals with sufficient space and funding, however, there are concerns about single-family room design: Is it safe? Will it require more staff? Will the additional upfront cost be offset by savings elsewhere? Enough hospitals have now built single-family rooms for some or all of their NICU beds and have conducted studies to answer many of these questions.[6]

DESIGNS THAT INCLUDE PARENTS AS PARTNERS IN CARE

As with private room design, the NICU has lagged behind other parts of the hospital in which family-centered care is a well-advanced concept, with family members rooming in and playing a major role in caregiving and medical decision making. To a large extent, the design and operational aspects of these concepts are closely connected. If the design features support a family's presence at the bedside of their infant, they are much more likely to participate in the infant's care[3] than if they feel unwelcome and in the way. Good design provides a place for the family to rest, work, and socialize without having to leave the NICU and allows families the opportunity for privacy without isolating them from other families or staff. These features are more easily accomplished with single-family rooms but can be achieved even in a more open design if there is sufficient space and creativity.

DESIGNS THAT SUPPORT NICU STAFF

Staff benefit from areas where they can work, collaborate, teach, and socialize without interfering with the needs of infants and families. Within the patient care area, this means that there must be dedicated space at each bedside for charting (including anticipation of electronic charting within the life span of all new construction), placement of equipment, storage of frequently used supplies, and performing procedures, along with appropriate task lighting, all arranged in a fashion that is ergonomically correct and does not interfere with the family space.

Away from the bedside, caregivers need additional space to meet and collaborate in a setting that encourages interaction with their colleagues while keeping them informed of the status of their patients through electronic monitoring and communication devices.

THE PLANNING PROCESS

Designing or renovating an NICU is a process that most medical professionals engage in only once or twice in their career. There are no "standard designs" because the footprint, budget, and culture of every NICU differ substantially from the rest. Often the architectural firm chosen for the project has little experience with modern NICU design as well. For these reasons, careful adherence to a planning process that ensures consideration of the major aspects of good NICU design is crucial. In Box 30-2, the key components of this planning process are outlined.

BOX 30–2 The Planning Process

DREAM:

- Assemble the team. Who are equal partners—and who are not? Disciplines that are not included from the beginning are often given the message that they are not on an equal level in the decision-making process. Most notable in this respect are parents, who are often not included until the "user group" stage.
- Determine the vision. How will the new unit change the culture, attitudes, processes, and lives of the people who are cared for and caregivers there? Recognize that this is a life-defining place for many people who pass through. How can the unit design facilitate the best outcomes for all constituencies?
- Review what you appreciate about your existing unit (e.g., collegiality, visibility, easy communication). Too often, a new unit is built to address the glaring inadequacies of the existing unit but creates new problems of its own because the benefits of working in close, open quarters are overlooked and therefore are not preserved with new strategies.
- Educate your team on change strategies. Building a new unit requires major changes for everyone, and achieving buy-in will be necessary at many points along the way.

DESIGN:

- Select an architectural firm, as well as any additional design collaborators (e.g., acoustical engineer, lighting engineer, interior design).
- Review what advantages and challenges a new location will give you. Typical constraints include financial and space limitations. Finding out about these after the design process is well-advanced can be the source of much frustration!
- Develop the functional program—identify all discrete areas needed, the amount of space needed for each, and desirable adjacencies and traffic patterns. Make sure you do not leave out areas that you may not have now but should include in a new unit, such as family support spaces, recycling area, and sufficient staff support space. All change is incremental, so spaces that do not exist or are grossly inadequate currently are often the hardest to get right—the tendency is to make the space larger but still inadequate.
- Design the patient room mockup concurrently with the floor plan—do not let the geography and space available dictate the ideal room size/layout any more than absolutely necessary.
- Additional activities that are important to initiate early in the design process:

Methods for communicating the progress of the design process to all staff for their input and buy-in.

Planning for the move, especially if interim space will be used during the construction process, or if the relationship of the neonatal intensive care unit to the labor, delivery, and recovery area will change.

Sustainable design/operation—many of these decisions will need to be made very early in the design process and would be very expensive to introduce later. This will lead to decisions about HVAC systems; floor, wall, cabinetry, and ceiling finishes; power supply and use; and so forth.

New communication systems/strategies for a larger, more private unit

Patient (monitor) to nurse

Nurse to nurse

New nursing collaboration/training opportunities/challenges/strategies

New supply access/storage/removal opportunities/challenges/strategies

New infection control opportunities/challenges

HIPAA/privacy considerations

Site visits—a very important component to "get right"—choosing at least a couple units to visit that have a similar size, acuity, and philosophy is important, but much can be learned from innovative units even if they are much different from your own, and even if they are in other parts of the hospital, such as pediatric or adult ICUs, or even some non-critical care facilities.

Equipment planning

BUILD:

Once the design is finalized and the unit is under construction, many months remain to prepare for the dramatic changes in culture and practice that can occur in a new unit. Teams that are already at this stage are probably best-off to review the above items in the "Design" stage and focus on any of those that still remain in an early stage, or may even have been overlooked until now.

Developed for use in the Vermont Oxford Network NICQ 2009 Improvement Collaborative.

CHAPTER 31

Biomedical Engineering Aspects of Neonatal Monitoring

Valerie Y. Chock, Ronald J. Wong, Susan R. Hintz, and David K. Stevenson

Monitoring in the neonatal intensive care unit (NICU) has improved dramatically since the inception of neonatology as a subspecialty. An increasing number of devices are used to alert the physician to developing problems and to direct complex care as technological advances assist in the management of sicker infants in the NICU. Although monitoring systems are diverse, they all should meet a few basic requirements. Systems should be reliable in the sensitivity and the specificity of the information relayed by the system and in long-term equipment integrity. They should be relatively simple to operate and provide information in an easy-to-interpret manner. The system must be safe for patient use, which is especially important in neonatal patients because the sensors or probes, the portion of the system that comes in contact with the patient, must be appropriately sized and nonirritating to sensitive skin. The ideal system should be noninvasive, or at least not require invasive procedures beyond those that are routinely needed for optimal patient care. The system should provide continuous, or near-continuous, real-time information, so that personnel may respond to an event occurring at the time the information is relayed. In addition, the system should be relatively small and portable. The monitoring system must be safe for personnel, and must not interfere with other vital equipment required for patient care.

To meet the aforementioned requirements, a monitoring system must be engineered appropriately and dependably. Monitoring systems have afforded enormous benefits to patients and to clinicians, and they have become such an integral part of the NICU environment that a basic understanding of the shortcomings of such equipment has been overlooked. Although the technical aspects of monitoring systems may not seem to be important when caring for patients, the clinician should be aware of the basic instrumentation and principles of operation for each of the systems and their potential limitations. This chapter reviews cardiac, respiratory, blood pressure, transcutaneous, end-tidal, pulse oximetry, and light-based spectroscopy monitoring.

CARDIAC MONITORING

In the modern NICU, heart rate and rhythm strip monitoring is considered to be the standard of care. This information, which may report the first warning sign of patient decompensation, is usually taken for granted. The electrocardiogram (EKG) is an indispensable tool, however, that delivers vital information simply and noninvasively to the physician regarding molecular and cellular events of the heart.

Biologic Basis

Electrocardiographic recording provides a one-dimensional view of the heart, based on time-dependent electrical potential changes between two points on the body.[74] The origin of this electrical signal lies in the transmembrane potential, the result of differences between the concentrations of ions inside and outside the cells; in a resting cell, this electrical difference is approximately −90 mV. When a cardiac cell is activated, a cardiac action potential occurs, consisting of a rapid depolarization followed by a period of repolarization (Fig. 31-1).

The rapidity of the depolarization phase, the slope of the repolarization, and the shape of this action potential differ depending on the cardiac cell type. The initial depolarization phase in cells of the His-Purkinje system is extremely rapid,

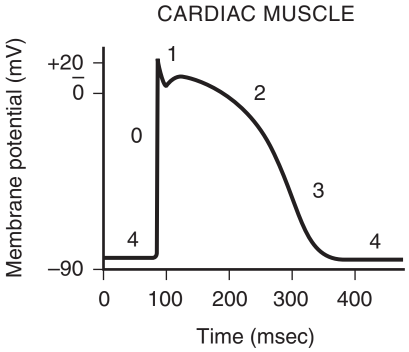

Figure 31–1. Cardiac action potential for a Purkinje fiber with phases 0 to 4 as marked. *(From Katz AM:* Physiology of the heart, *2nd ed, New York, 1992, Raven Press.)*

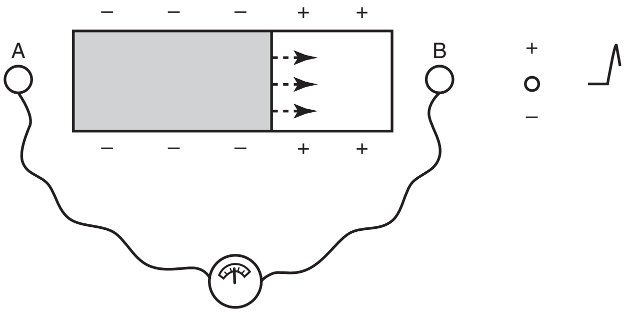

Figure 31–2. Wave of depolarization in a strip of myocardium after stimulation on the left side. Electrode *B* is facing a greater positivity than electrode *A,* and an upward deflection is observed in the chart recorder at right. *(From Katz AM:* Physiology of the heart, *2nd ed, New York, 1992, Raven Press.)*

but it is much slower in nodal cells. These electrical changes in cardiac cells are the result of the opening and closing of complex ion channels in the cell membrane, first postulated by Hodgkin and Huxley in the 1950s.[63] They are now known to be regulated not only by electrical impulses, but also by selective gene expression. In the normal heart, an electrical impulse arising in the sinoatrial node is propagated through the atria, then the ventricles, ending at the area around the outflow tracts. It is more difficult to explain how the spreading depolarization and repolarization of cardiac cells are translated into an EKG. The theory most often cited to explain this phenomenon is referred to as the "dipole theory."[51]

A *dipole* is an electrical source that is asymmetric with respect to charge. As discussed earlier, the outside of a myocardial cell at rest is positively charged compared with the cytosol, whereas during excitation, depolarization occurs *within* the cell, and the outside then becomes negatively charged in comparison. The heart during excitation, when viewed from the surface, can be considered a dipole because excited myocardium is negatively charged with respect to the myocardium at rest. Clinical application of this principle is possible because the heart is surrounded by tissues of the body that act as conductors for electrical current. The potentials generated by the dipole, in this case the heart, may be measured at the body surface by a recording electrode, or lead. From this background, a surface lead placed facing an approaching wave of excitation would record a "positive" potential, which is represented on the EKG as an *upward* deflection (Fig. 31-2). Although the dipole theory is useful for understanding how cardiac electrical activity is detectable on the body surface, it is an oversimplified explanation because the tissues surrounding the heart are inconsistent conductors, and the heart is not truly a single dipole, but rather multiple dipoles.

Leads and Lead Placement

It is not obvious how a lead placed on the surface of the body transmits information regarding the electrical activity of the heart. Simply stated, a lead is an electrode consisting of metal that forms a connection from the heart, which is a system involving electrical conduction, to the instrumentation.[27] For this process to occur, a *redox,* or reduction-oxidation reaction, must occur at the electrode surface, allowing for energy conversion, which is made possible by the reversible transfer of ions from a metal into an electrolyte solution. Theoretically, this completely reversible system describes an electrode in which the change in equilibrium potential is zero; however, in reality, there are several problems that can cause an electrode to operate irreversibly, at which point it is said to be polarized. Polarization can result in practical difficulties in using electrodes for biologic monitoring. One cause of polarization is referred to as "charge-transfer overvoltage," which results when the transfer of ions from the metal into solution does not balance the deposition of ions on the metal surface. This imbalance is caused by differences in how much energy is required to deposit ions onto a metal surface, and can vary with different metal types. Another potential cause of polarization is "resistance polarization," which describes changes in the potential of an electrode system owing to films that have accumulated, or changes in the concentration of electrolytes in the diffusion layer. These changes could be caused by the production and deposition of electrolytes or other ionic species by the body.

The type of electrode used for clinical application has been a matter of intense study and research over many years.[50] The hydrogen electrode, which is a platinized electrode bathed in an acid solution with hydrogen gas bubbled through it, is the most reproducible. It is used as the zero potential standard against which all other electrodes are measured, but it is inappropriate for clinical use. In his early studies, Einthoven's approach was to immerse the arms and feet of his human subjects into buckets filled with saline, using the arms and feet as electrodes. Of primary importance in the development of clinically useful electrodes was the investigation of metals, however, in which electrode-electrolyte interfaces resulted in the smallest and most stable voltage potential because this potential and its variations can be responsible for significant artifact. Researchers made numerous other observations, including that a uniform film of electrolyte-containing material on the electrode decreases this noise or artifact. For this reason, silver–silver chloride electrodes are extremely useful for noninvasive measurements in the clinical arena because they are extremely stable and the most reliable electrodes next to hydrogen electrodes. Silver–silver chloride electrodes can be prepared in various forms, and they have been developed for special use in the NICU setting.

The most popular type of electrode used for EKG monitoring in the NICU is a silver–silver chloride, foil-based, recessed or floating electrode. When using this type of electrode, the metal does not come into contact with the subject directly; contact with the patient is instead made through an electrolyte solution. In the past, the metal electrodes were placed on the patient after separate application of an electrolyte paste or gel. Numerous companies now market very flexible, prewired neonatal and pediatric EKG monitoring electrodes in which cloth surrounds the small silver–silver chloride electrodes with the lead already attached to a safety socket. These types of units are backed by a sticky adhesive electrolyte gel, referred to as *hydrogel,* the precise composition of which varies with each manufacturer. The hydrogel serves as the required electrolyte interface solution and the reversible adhesive. These electrodes are usually packaged in sets of three, are relatively inexpensive, and are designed for one-time use.

Neonatal probe placement is a unique area of concern that requires special consideration. Improper lead placement is a particular problem in premature infants because the shape of the thorax yields a limited flat surface for electrode placement. In addition, the premature infant's small size markedly restricts the space available for lead placement, occasionally resulting in electrodes that are placed too close to each other or at right angles to the main P and QRS vectors. Additional problems are encountered when many noninvasive surface monitors and other equipment prevent proper placement of electrodes, leading to worrisome artifacts caused by patient movement or manipulations. Tremulousness and myoclonic seizures have been reported to simulate atrial flutter in newborns. EKGs performed during chest percussion have been mistaken for tachyarrhythmias.[111]

The most common causes of EKG artifacts are related to poor skin contact with the electrodes: (1) poor adhesiveness resulting from multiple probe replacement; (2) poor positioning on a nonflat thoracic surface, such as a bony prominence; and (3) poor contact resulting from excessive lotion or gel on the skin surface. Few studies have investigated optimal EKG probe location on a neonate's body surface. In practice, lead placement for the patient in the NICU is frequently dictated by issues such as the position of other necessary equipment or probes on a small patient. Baird and colleagues[9] studied the best positioning of leads for respiratory and EKG signals in term and preterm infants. They found that the best EKG signal was found with one lead at the right midclavicular line at the level of T4 and the other at the xiphoid in term infants, whereas lead placement in a line parallel, but shifted to the left, was best in premature infants (Fig. 31-3).

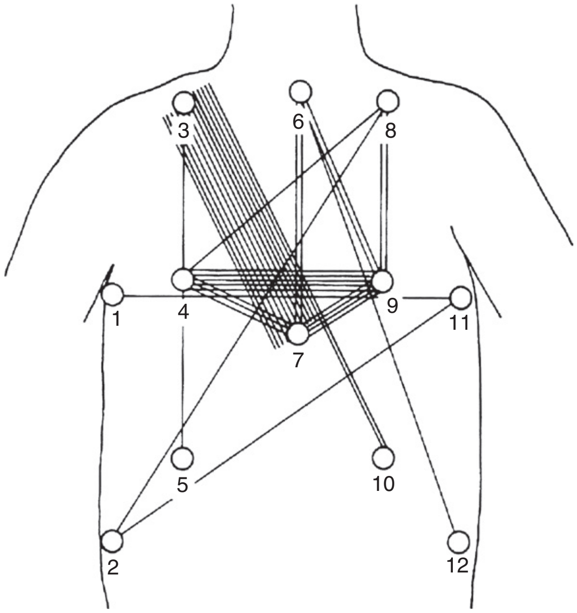

Figure 31–3. Optimal locations for cardiopulmonary monitoring electrodes on preterm and term infants. Electrodes between positions *3* and *7* usually have the best results. *(From Baird TM et al: Optimal electrode location for monitoring the ECG and breathing in neonates,* Pediatr Pulmonol *12:247, 1992.)*

Also of great importance in the consideration of EKG probe placement is the fragility of the skin of the patient, especially in the case of a premature infant. Previous reports have emphasized the possibility of skin damage with adhesive-based probes, specifically EKG probes, in premature infants. In extremely premature infants, removal of adhesive probes has been associated with stripping of the stratum corneum layer, which may be associated with increased permeability to toxic chemicals and serve as a site of entry for infectious agents.[57] Transepidermal water losses (measured using an evaporimeter technique) have been shown to be extremely high in areas of the skin of preterm infants on which traditional adhesive probes were placed and then removed.[25] This water loss may result in substantial clinical complications, especially in the most premature infants whose epidermal barrier is already weak and whose water losses are significant. Other types of skin injury, such as anetoderma, have been identified in association with EKG probe placement in preterm infants and infants with extremely low birthweight, and may be linked to cleansers or irritants trapped under the adhesive or to local hypoxemia.[29]

Electrocardiogram Device and Safety

Most nurseries now use computer-based cardiac monitoring systems. These systems have obvious advantages over older devices: They can store information in memory, providing the opportunity for trend analysis and review; they frequently possess the capability to assess more complex EKG parameters, allowing for recognition of specific rate and rhythm disturbances; they usually have more sophisticated filtering components and can reduce noise and artifact; and they allow for multiple patient parameters to be viewed on a single display with the availability of blood pressure, pulse oximetry, and other computer modules.

A typical, simplified EKG module diagram is shown in Figure 31-4. As the EKG signals pass from the patient to the

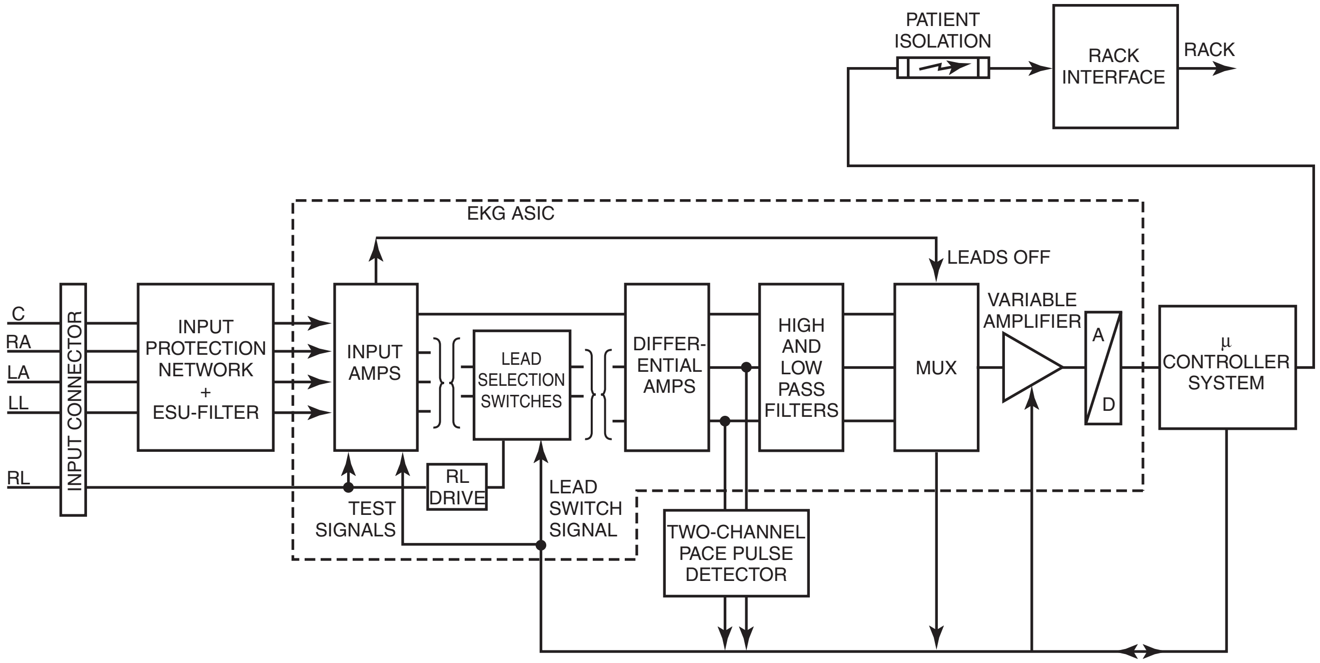

Figure 31–4. Block diagram of a typical electrocardiogram (EKG) module monitoring system. *(Courtesy of Hewlett-Packard Corporation and Agilent Technologies, Palo Alto, CA.)*

monitor through the electrode leads, an input protection network provides electrical isolation, preventing electrical shock to the patient, and filters extraneous high frequency signals from the rest of the system. The signal is next selected with respect to lead, then amplified. In many systems, the common mode signal from behind the lead selectors is used to drive the right leg amplifier to prevent interference from 60-Hz power lines, a common source of artifact. High and low pass filters usually are used, allowing for independent selection of diagnostic, monitoring, or filter bandwidths for each channel. Finally, an analogue-to-digital (A/D) circuit converts the signal to one that can be presented to and understood by the microprocessor. The microprocessor then routes the signal to other ancillary modules for further processing by specialized evaluation algorithms.

Troubleshooting problems with EKG monitoring should be approached in a systematic fashion. The most important causes of artifact are often simple to correct, however, such as poor contact between skin and electrode or improper placement of leads. Problems with the EKG equipment, including cables and cable connections, or, less likely, internal hardware or software failure in the EKG module, also may be contributory. Finally, electrical interference from other equipment may lead to artifact (Box 31-1).

Recommendations for safe current limits for electrocardiographs have been set by the American Heart Association (AHA).[82] These recommendations address two aspects of electrical safety. First, the level of current allowable to flow through any patient-connected lead has been established at 10 μA. This recommendation is based on studies by Watson and associates,[126] which showed that the smallest current needed to produce ventricular fibrillation through an endocardial electrode in humans is 15 μA, and it was considered to be unrealistic from an engineering standpoint to establish a limit lower than 10 μA. Second, the recommended allowable chassis leakage current, or the unintentional current that flows from the electrocardiograph to ground, has been established at 100 μA. A limit of 10 μA is the optimal goal because of the small potential for the patient to contact the monitor case either directly or indirectly while being simultaneously grounded through another pathway; however, with the increasing technical complexity of monitoring systems, design challenges meeting this standard are prohibitive.

BOX 31–1 **Potential Causes of Electrocardiogram Artifact**

- Improper electrode placement
- Poor skin contact
- Patient movement: hiccups, myotonic jerks, seizures, tremors
- Improper lead selection
- 60-Hz interference
- Electrical interference from other equipment or appliances
- Internal electrocardiograph module hardware or software failure

BLOOD PRESSURE MONITORING

Blood pressure monitoring of a newborn can be undertaken using various methods and technologies.[79] Depending on the clinical requirements, blood pressure may be measured continuously and directly through the use of electrical transducers and catheters, or indirectly through the use of occlusive devices (cuffs) and manual or automatic methods of detecting pulsations.

Direct Monitoring

Most direct blood pressure monitoring devices used in the NICU incorporate the "catheter-type" transducer. In these devices, fluid exerts a force against a diaphragm, and the sensed deflection of the diaphragm is relayed as an electrical signal. The early versions of these instruments were cumbersome; were extremely expensive; and, because they were reusable, had to be sterilized between each use. The advent of solid-state construction has allowed for smaller, less expensive, and disposable transducers.

A pressure transducer is simple in concept, but it is a complicated system in reality. According to Pascal's law, a pressure transducer would detect the same pressure as that seen at the distal tip of a fluid-filled tube (e.g., a catheter) as long as the two are at the same level. This law applies only for static pressures, however. Because blood pressure represents a complex oscillating pattern, other factors influence the response of the catheter-transducer unit, including the mass of all components; the stiffness or compliance of the "elastic" component of the transducer, which is described by the number of cubic millimeters of fluid required for the application of 100 mm Hg; and the viscous drag, also referred to as "damping," which represents a retarding force that is proportional to the velocity of movement of the fluid in the transducer-catheter system. These factors are related to pressure by the following equation:

$$(\mathrm{M})\ \mathrm{d}^2\mathrm{x}/\mathrm{dt}^2 + (\mathrm{R})\ \mathrm{dx}/\mathrm{dt} + \mathrm{Kx} = \mathrm{P(t)}$$

where M = effective mass, x = distance moved, R = viscous drag factor, K = stiffness, and $P(t)$ = pressure applied.

Although seemingly complicated in this form, this relationship is simple compared with the actual case in which the viscous drag of the fluid in the transducer must be considered separately from that of the fluid in the catheter, which is influenced by resistance of the catheter. Distortions could exist in the system so that additional undulations not truly relayed at the tip of the catheter could be detected at the level of the transducer. This artificial detection could lead to a problem known as "overshoot," which causes the transducer to read a pressure higher than that at the catheter tip. The degree to which this potential problem exists is influenced by the viscous drag or damping factor, which is proportional to the viscosity of the fluid, the square of the catheter length, and volume displacement, and is inversely proportional to the catheter diameter cubed and the square of the density of the fluid. If the damping factor is 1, there would be no overshoot, but the rise time would be unacceptably long. A damping factor of 0 is impossible and undesirable; the amplitude of the wave at the transducer in this case would become larger and larger. In practice, systems with damping factors of approximately 0.7 are used.[27]

Clinically, it is well known that air bubbles in the system also can significantly influence the performance of the device because air is compressible, and its presence would increase the volume displacement and lead to an increased damping factor and prolonged rise time. This problem may be of particular concern when, as in most cases, the same catheter is used for infusion of fluids and medications. In addition to artifact, introduced bubbles could cause significant, potentially life-threatening patient complications, especially if air is introduced to the arterial or venous side in the case of central venous pressure monitoring. Distortion may be caused by movement of the catheter. Although actual pressure is the same at the catheter tip, low frequency oscillations may be produced by movement of the catheter tip in the vessel. This type of artifact often is easily detected and usually addressed simply with catheter stabilization.

Arterial and venous pressures can be measured by catheter-transducer systems. In a neonate, these measurements are usually accomplished by accessing the umbilical vessels, introducing flushed catheters into the appropriate vessels, then placing a transducer at the proximal end of the catheter. Care should be taken so that the transducer is at the level of the distal tip of the catheter. For most transducer sets, establishing a "zero" pressure reading before obtaining meaningful patient data is necessary. As with all transducers, a signal is passed through isolation before analysis by the remainder of the system. In the case of pressure monitors, mean blood pressure is calculated, which is not the simple arithmetic average of systolic and diastolic pressures, but is the area under a single pulse wave divided by the width of the pulse. Alarm systems are also incorporated into typical modular blood pressure monitors, allowing for selection and setting of systolic, diastolic, or mean pressure alarm points.

Indirect Monitoring

Indirect blood pressure monitoring is accomplished through use of an occlusive device, usually the familiar "cuff" that contains an inflatable bladder with a tube for entrance and exit of air. The cuff is placed around an extremity and is inflated to an adequately high pressure to cause occlusion of arterial flow distal to the cuff. The placement of the cuff on either the upper arm or calf, two popular sites in preterm infants, has not been shown to result in significant differences in blood pressure readings in these patients.[79] During the deflation of the cuff, measurements may be obtained regarding systolic and diastolic blood pressure levels.

Selecting the proper cuff size is crucial and cannot be overemphasized.[6] The AHA recommends that a cuff width approximately 40% of the member circumference be used; using a cuff that is too narrow may result in blood pressure measurements that are falsely high because the pressure in the cuff could be high compared with the underlying tissue. In addition, the cuff should be applied snugly because a loose cuff may provide falsely high values, and it should be at the same level as the heart when making measurements. Numerous cuff sizes are now available for neonatal patients making selection of the correct size easier.

The most commonly taught method of indirect pressure monitoring is the auscultatory method, in which the examiner rapidly inflates, then slowly deflates the cuff while listening for distal Korotkoff sounds with a stethoscope. This method is not useful in neonates because the frequency spectrum of arterial sounds in this age group cannot be routinely heard. The most frequently used method to assess blood pressure noninvasively in a newborn is the oscillometric method (Fig. 31-5). In this method, cuff pressure is increased

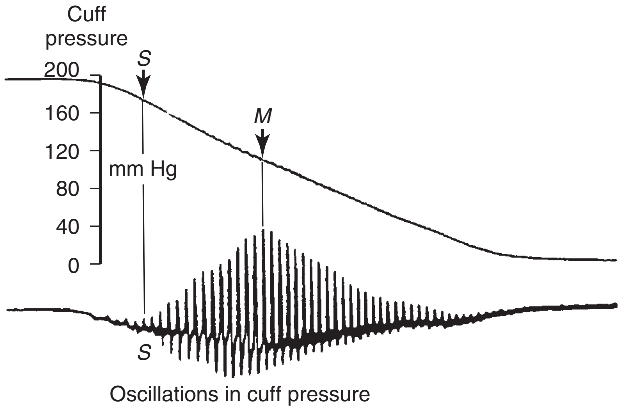

Figure 31–5. Oscillometric method of blood pressure monitoring. M, mean pressure; S, systolic pressure. (*From Geddes LA:* Cardiovascular devices and their applications, *New York, 1984, John Wiley & Sons. Reprinted by permission of John Wiley & Sons, Inc.)*

quickly to above the systolic blood pressure. As pressure is slowly released from the cuff, the cuff pressure approaches the systolic pressure, and the artery begins to pulsate; the small pulsations or oscillations are communicated to the arterial pressure sensor through the edge of the cuff. A pressure sensor also exists in these systems to monitor the true pressure of the cuff. When the cuff pressure decreases to less than the systolic pressure, blood rushes into the artery, causing oscillations to be larger. With continued deflation, the oscillations become larger as more blood flows into the tissue until a maximum point very close to the true mean arterial pressure of oscillation is reached.[49] Oscillations continue to decrease as cuff pressure is slowly decreased.

In addition to pressure sensors, these devices have pressure pumps and deflation systems that are controlled by microprocessor technology. The oscillatory signals are extracted, then converted to a digital signal and analyzed by the microprocessor. Systolic and diastolic blood pressures are deduced through extrapolation, using attenuation rate of signal on both sides of the maximum oscillatory readings and often internal reference measurements. Each system has a slightly different algorithm, and differences in readings among devices and between the oscillometric and direct methods have been shown in newborn patients.[52,97] Many systems have timing modes that allow for frequent automatic readings, and many systems now offer multiple patient modes, allowing for selection of adult, pediatric, or neonatal parameters. Mode selection is most important in terms of cuff inflation and overpressure maximum safety limits controlled by the microprocessor.

Indirect blood pressure monitoring may be ideal in certain clinical situations in the newborn nursery, but there are important issues to consider. First, although indirect blood pressure monitoring is noninvasive, it is a noncontinuous method. In specific instances of critically ill infants, direct and continuous monitoring may be required. Second, this method is extremely sensitive to patient movement; gentle restraint often is needed to obtain a reliable reading. Finally, a full range of cuff sizes should be available to ensure accuracy of readings.

MEASUREMENT OF CARDIAC OUTPUT

The measurement of cardiac output and the perfusion of tissues, and delivery of oxygen (if the oxygen saturation is known), is the ultimate goal of cardiac monitoring. Even invasive techniques, employing the Fick method, are challenged in a newborn because of ductal shunting, which can vary considerably in the transitional period after birth, influenced by many endogenous and exogenous factors. Electrical cardiometry, which depends on continuous measurement of thoracic electrical bioimpedance, can be used to estimate stroke volume. Electrical velocimetry is a refinement of this technological approach.[95,96,107,114,135] Nonetheless, the ductus arteriosus remains a vexing variable for these minimally invasive technologies, which are easily applied to an adult whose heart is physiologically a pump in series, uncomplicated by fetal cardiac shunts. Portable high resolution, three-dimensional and four-dimensional cardiac imaging by ultrasound with semiautomated computation of ventricular function, right ventricular and left ventricular chambers, and stroke volumes offers promise, however, of better continuous monitoring of critically ill neonates.[16,86]

RESPIRATORY MONITORING

Respiratory assessment and monitoring are essential in the NICU. Although physical examination can provide information regarding the quality of an infant's pulmonary effort, it is a noncontinuous evaluation. Continuous monitoring is crucial in an ill patient, but the quantity of information varies greatly with the method used. Surface monitoring techniques are used routinely in the NICU to monitor respiratory rate, but they are unable to provide detailed information regarding further pulmonary parameters and are often subject to artifact. Methods of sensing ventilation requiring tight connections with the patient's airway often provide the most data, but they are invasive and, until more recently, were impractical for continuous use. It is important for all care providers to understand the benefits and limitations of the respiratory monitoring systems used in the care of their patients (also see Chapter 44, Part 2).

Surface and Noninvasive Monitoring

The most frequently used method of indirect monitoring in infants is transthoracic electrical impedance. This method measures electrical impedance changes between two electrodes on the thorax during respiration. The signal obtained could potentially be dominated by the signal generated by the polarization layer in the electrodes, so a high frequency current (>25 kHz) is passed though the electrodes to minimize this possibility. By using this modulation technique, the same electrodes that are used for EKG measurement can be used for respiration detection in many devices. The impedance change caused by breathing activity is extracted from the baseline impedance of the thorax, amplified, and converted to digital form to the microprocessor. Depending on the device being used, the microprocessor then performs numerous functions, including analyzing the signal for apnea and high and low respiratory rates, alarm triggering, and presenting the analyzed rate for display on the monitor.

The change in impedance with breathing can be very small with respect to the baseline thoracic impedance. Introduction of artifact, commonly seen with improper lead placement, poor skin contact, or patient movement, is a frequent problem with this approach to respiratory monitoring. In the case of obstructive apnea, a breathing movement may be detected when no breath truly has been taken. In addition, transthoracic changes in electrical impedance are caused by other physical changes not related to respiration, and these changes also may lead to incorrect signal display or false alarms. Although impedance changes related to EKG signals are filtered out by specialized signal-processing algorithms in most microprocessor-based monitors, other changes in thoracic blood volume may result in transthoracic impedance changes. These changes may be detected, processed, and reported as a breath when no breath has been taken, or they may lead to a missed breath when one has actually occurred. Alarms may be triggered falsely as a result; conversely, no alarm may sound when an apneic event has occurred.

Inductance plethysmography is another indirect method for monitoring respiration. This technique involves the placement of a one-turn electrical wire coil around the chest and abdomen of the infant. The coil is incorporated into an elastic strap that conforms to the curvature of the infant. An electromagnetic property of each coil, known as the inductance, varies with the area outlined by the coil. This property is measured and yields signals that are proportional to the changes in area of the thorax and abdomen as the infant breathes. This signal can be used to detect apnea and to report breath rate. Theoretically, this method could provide a signal proportional to tidal volume, giving an indirect estimate of this parameter.

Other Monitoring Techniques

Highly sophisticated ventilatory techniques and continuous monitoring systems that have been available for adult patients for many years are now being integrated into the NICU. With increasing interest and concern regarding the influence of differing ventilatory strategies on long-term pulmonary outcomes, coupled with significant technological advances, continuous pneumotachygraphy now is frequently encountered in the NICU. Sensors, or transducers, that have been developed to detect signals such as airflow and pressure are placed in series with the airway.[34] These signals are converted to an electrical analogue signal, then amplified, and filtered. The signals are first processed by an A/D converter and then presented to the microprocessor, which processes the data further with respect to computational tasks, alarm triggering, and other factors (Fig. 31-6). The processed information is displayed on a monitor. The two basic categories of sensors most commonly used for neonatal pulmonary monitoring are flow and pressure sensors.

Flow sensors are classified by how the transducer obtains information as differential pressure or heat. The most common type of differential pressure sensor is one based on a fixed orifice within a tubular attachment placed in series with the airway. Pneumatic transmission lines are placed upstream and downstream of the fixed orifice, and a differential pressure is detected between them by the transducer. The flow rate can be calculated because the differential pressure signal is proportional to the square of the flow rate. Volume calculations can be undertaken by the microprocessor.[35] Another type of differential pressure sensor is the Fleisch, or laminar flow type, in which many capillary tubes, or in some cases a screen, are between the pneumatic transmission lines. The differential pressure across these tubes is almost linearly proportional to the flow rate. Because of the mathematical relationships used to solve for flow, the Fleisch differential pressure sensors may be more accurate over a wider range than the fixed orifice type. Capillary tubes are more likely, however, to have problems with moisture or secretions.

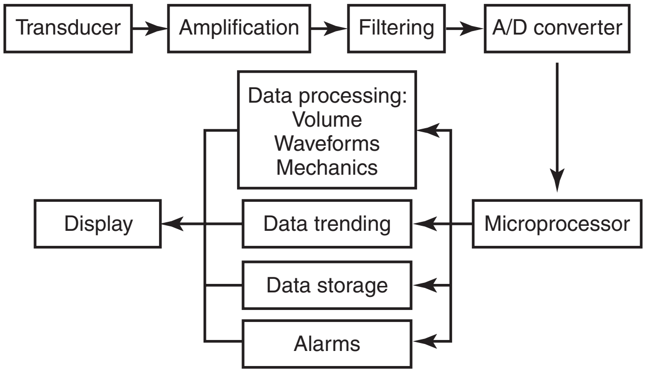

Figure 31–6. Simplified block diagram of a respiratory monitoring system.

Another category of flow transducer, based on the properties of heat convection, is the thermal anemometer. In these transducers, an element secured within a tube placed in line with the airway is heated continuously. As air flows past the heated wire or film, the element cools. Electrical current is delivered to the element to attain the elevated temperature again. The amount of current required is proportional, however, nonlinear, to the gas flow. A second heated element is added to the system if bidirectional flow measurement is needed. These devices are accurate over a wide range, but they may be prone to difficulties stemming from particulate matter or secretions. Pressure transducers are constructed so that a thin diaphragm is flexed in response to pressure. A sensing element associated with the diaphragm transmits the information regarding the amount of displacement sensed. The material used for the sensing element changes its electrical characteristics proportional to the strain applied. This same basic technology is used for airway and esophageal pressure transducers.

An increasing number of mechanical ventilators targeted specifically for use in neonatal patients now include pulmonary function graphics monitoring capabilities (see Chapter 44, Part 2). These graphics, including pressure-volume loops, flow-volume loops, flow waves, pressure waves, and volume monitoring, may be continuously displayed on a screen intrinsic to the ventilator itself, or on a laptop computer connected to the ventilator. Trending capability over many hours is available for various pulmonary function parameters in most of these newer devices. Monitoring loops and pulmonary function parameters continuously and in realtime may allow the clinician quickly to detect problems such as overdistention and changes in resistance and compliance. Clinical issues leading to these problems may be rapidly recognized and addressed, and patient response to therapy may be closely observed.

The most vexing problem for a clinician monitoring the assisted ventilation of a newborn is air leak around the endotracheal tube, which can be large and variable. This single uncontrolled variable in a newborn makes various measurements unreliable compared with measurements in older children or adults, in whom cuffed endotracheal tubes can be used.

TRANSCUTANEOUS OXYGEN AND CARBON DIOXIDE MONITORING

Transcutaneous blood gas monitoring is a concept that has been considered and studied for many years.[22] After the development of clinically useful sensors in the late 1960s, patient investigations followed, focused especially on newborns, owing to skin permeability to gas and the need for noninvasive monitoring devices.[69] Although subsequent technical advances have made their use for long-term monitoring less widespread, these systems are still used routinely in many nurseries (see also Chapter 44, Part 3).

Oxygen Monitoring

Transcutaneous oxygen tension ($Ptc{O_2}$) measurement is based on the principle of extracellular oxygen diffusion across the skin. These systems use electrodes, separated from skin and isolated from room air by an adhesive, semipermeable membrane. The oxygen from the skin reacts with the platinum–silver chloride sensor to create an electrical current proportional to the concentration of oxygen. This signal is relayed by a cable to the device, where further analysis and display functions are carried out. Because measurements are made transcutaneously, electrodes are best placed on an area of the body where the epidermis is thin, and capillary network is dense. Even with this proviso, $Ptc{O_2}$ does not approach correlation with $Pa{O_2}$ unless the capillary bed is arterialized through heating; systems provide for electrode heating to 43°C to 44°C before placement. These systems require calibration before each use and recalibration every 2 to 6 hours depending on the system and clinical circumstances. Studies have shown a linear relationship between $Ptc{O_2}$ measurements and $Pa{O_2}$, although values may be discrepant in neonates at high or low $Pa{O_2}$ levels, and accuracy differs among different instruments.[24,36]

Several factors may be associated with inaccurate $Ptc{O_2}$ readings. The sensor must be placed on well-perfused skin, which may be exceedingly difficult with an infant with septic or cardiac shock or other conditions in which local hypoperfusion may be present. The skin site chosen also may not be maximally permeable to gas if scarring or edema is present, or if the site chosen is covered with thickened skin. The sensor and device must be properly prepared, placed, and calibrated before making measurements. Air bubbles under the sensor, an insecure seal with the skin, or faulty calibration may be responsible for inaccuracies. Because of these potential problems, clinical correlation of $Ptc{O_2}$ readings with arterial blood gases should be undertaken. $Ptc{O_2}$ monitoring has been associated with some dermatologic complications[22,53]; care must be taken to move sensor position and inspect underlying skin frequently and to avoid placement of sensors on infants with gelatinous or fragile skin.

Carbon Dioxide Monitoring

Transcutaneous carbon dioxide ($Ptc{CO_2}$) monitoring is possible through the use of a pH-sensitive glass electrode with a silver–silver chloride reference electrode. Carbon dioxide (CO_2), which diffuses through the skin and a semipermeable membrane attaching the sensor to the skin, causes analyte pH changes that result in an electrical signal, which is relayed through a cable to a device for further analysis and display. Heating the skin is not as crucial for $Ptc{CO_2}$ determination, but heated electrodes have been shown to provide better correlation of $Ptc{CO_2}$ with $Pa{O_2}$, although transcutaneous measurements are consistently greater than arterial values. Calibration for these systems is required, and calibration time and response time are improved when heated electrodes are used. Combined $Ptc{CO_2}$ and $Ptc{O_2}$ sensors are available, although some debate exists regarding the possibility that single electrodes may perform slightly better.[41] $Ptc{CO_2}$ monitoring systems have shown better sensitivity and specificity in the detection of hypercarbia than hypocarbia in term and premature infants, and different systems have slightly different levels of accuracy.[24,41,78] In contrast to $Ptc{O_2}$ readings, which may be falsely low in scenarios of poor perfusion, $Ptc{CO_2}$ readings are likely to be falsely high. Concerns regarding sensor placement and $Ptc{CO_2}$ system calibration are similar to those of $Ptc{O_2}$ devices. The potential for skin injury also exists with these systems.

CAPNOGRAPHY

Another noninvasive alternative to blood gas monitoring for estimation of $Pa{CO_2}$ is capnography. Capnography is the continuous measurement of the partial pressure of expired respiratory gases ($Pet{CO_2}$). Although there are several possible methods for assessment of $Pet{CO_2}$, infrared (IR) spectrography is the technique most frequently used because it allows for a compact and relatively inexpensive device.[17,119] Capnography is based on the principle that CO_2 molecules selectively absorb IR light at specific wavelengths (4.3 μm). The devices must contain an IR light emitter or source and photodetectors; IR light absorption, which is proportional to the concentration of CO_2, can be determined. Most of these devices use emitters that produce a continuous spectrum of IR radiation that is much broader than the narrow absorption region of CO_2, making it necessary to use an optical interference filter. Conventional capnographs usually display $Pet{CO_2}$ (in mm Hg) and a waveform or capnogram.

There are two basic configurations for these devices: mainstream and sidestream. In mainstream systems, the sensor is placed in an airway adapter so that respiratory gases are measured directly from the patient breathing circuit. In sidestream systems, a sample of expired gas is aspirated from the patient breathing circuit into a sampling tube and analyzed by the sensor, which is remote from the circuit. Several issues common to most devices can affect the accuracy of measurement.

Water vapor may produce erroneous measurements by condensing on the detector and absorbing IR light, a problem that has been addressed by heating the detector to above body temperature. Moisture or secretions may also clog the airway adapter or expired gas sampling line. This potential problem has been ameliorated with vertical positioning of the sampling line, or placement of filters on the sampling line. In addition, mainstream systems cannot be used for nonintubated patients.[18,43,101]

Capnography, providing continuous and noninvasive measurements, has become an important aspect of monitoring for adult and pediatric patients. This type of monitoring has become the standard of care for patients under anesthesia in the operating room,[3] and has been used extensively in adult and pediatric intensive care environments.[1,19,106] Technical considerations have previously limited capnography use in neonatal patients. Generally, the presence of lung disease influences the accuracy of capnography systems, with PetCO$_2$-PaCO$_2$ correlation better among patients without pulmonary injury.[67] High-flow sidestream systems can produce falsely low PetCO$_2$ results because of the low tidal volume and high respiratory rates of infants and the comparatively large sample cell of the device.[30,77] Mainstream devices may increase dead space and compete for tidal volume. Early studies in neonates suggested that elevations of PaCO$_2$ and PtcCO$_2$ could result from the presence of a mainstream device in the ventilator circuit, possibly because of a rebreathing phenomenon.[39,87]

Advances in mainstream and sidestream technologies have made capnography more applicable for use in the NICU. Mainstream devices with significantly reduced dead space have now been developed (<0.5 to 1 mL). Rozycki and colleagues[105] used a mainstream device (Pryon SC-300; Pryon Corporation, Welch-Allyn, WI) to assess the accuracy and precision of PetCO$_2$ measurements in 45 intubated preterm infants using over 400 PetCO$_2$-PaCO$_2$ comparison pairs. Overall, the correlation of PaCO$_2$ and PetCO$_2$ was good, with a correlation coefficient (r) of 0.833. This relationship was noted to be better than that reported for capillary samples compared with PaCO$_2$.[113] PetCO$_2$ tended to be lower than PaCO$_2$ by approximately 7 mm Hg. In this study, a clinically "safe range" for PaCO$_2$ of 34 to 54 mm Hg was prospectively identified by the authors; the PetCO$_2$ indicated that the PaCO$_2$ was within this range 91% of the time. The end-tidal measurements were accurate in predicting true "hypocarbia" or "hypercarbia" only 63% of the time, however. PetCO$_2$ was not as accurate at the high or low range. The authors further found that patient ventilation index had the strongest influence on measurement bias (at least 5 mm Hg difference in PetCO$_2$ and PaCO$_2$ measurements), suggesting that as lung function worsens, the usefulness of PetCO$_2$ monitoring may also decline. Nonetheless, within proscribed parameters, PetCO$_2$ monitoring was shown to be useful for trending, and possibly helpful in alerting the clinician to potential hypocarbia or hypercarbia.

Wu and colleagues[130] studied a low volume dead space mainstream device (CO$_2$SMO Plus-8100; Novametrix Medical Systems, Wallingford, CT) in 61 term and preterm patients with respiratory and cardiac disease, assessing accuracy in 130 PetCO$_2$-PaCO$_2$ comparisons. The authors found that PetCO$_2$ slightly underestimated actual PaCO$_2$ in general. Overall correlation of PaCO$_2$ and PetCO$_2$ was still strong ($r = 0.818$), however, and was similar in term and preterm infants. Although sample size was limited, and the authors did not present specific analyses at high or low ranges, the Bland-Altman plots[21] seemed to indicate that the accuracy of PetCO$_2$ could be diminished during periods of true hypocarbia or hypercarbia. Mainstream capnography has also been shown to be useful in delivery room resuscitations, allowing for consistently accurate and significantly more rapid determination of tracheal and esophageal intubation than afforded by clinical examination.[103] Although in this study tracheal intubation was considered to be successful by the presence of a normal capnographic wave (Tidal Wave Sp; Novametrix Medical Systems), disposable colorimetric devices for CO$_2$ detection are now widely available.

Improvements in the sidestream capnography approach have also allowed for application in the NICU. Microstream (Oridion Medical Inc., Needham, MA) is a technology that attempts to overcome several problems common to other sidestream systems, a few of which are particularly important for neonatal patients.[30] In contrast to other devices that use broad-spectrum IR emitters, Microstream systems use a laser-based technology to generate an IR emission that matches the absorption spectrum of CO$_2$. The sample cell is significantly smaller than in traditional sidestream systems, and flow rate is lower, but response time has been preserved. These changes eliminate the challenges of competition for tidal volume and falsely low CO$_2$ readings, which are particularly problematic for neonatal patients. Hagerty and coworkers[56] evaluated the accuracy of this system in 20 intubated preterm and term infants, with and without pulmonary disease. As seen in other studies, PetCO$_2$ measurements tended to underestimate PaCO$_2$, and were less accurate among patients with primary pulmonary disease (7.4 ± 3.3 mm Hg) than without (3 ± 2.4 mm Hg). The authors also assessed capnograph waveform parameters and found that specific waveform predictors independently differentiated infants with pulmonary disease from infants without.

Further large-scale investigations are needed to define better, and perhaps improve the accuracy of, end-tidal monitoring systems in neonatal patients, especially at the extremes of the PaCO$_2$ range. Similarly, the usefulness of the capnograph waveform in clinical management remains to be thoroughly studied. The impact of moderate to large endotracheal tube leaks on monitoring data also requires clarification. The benefits of rapid results and the truly noninvasive nature of capnography must be weighed against the known imprecision of PetCO$_2$ measurements compared with actual patient PaCO$_2$. At present, capnography may be useful in the NICU as a trending device, allowing for adjustment of ventilator support to keep PetCO$_2$ in an optimal range. If capnography indicates hypocapnia or hypercapnia, a blood gas measurement should be obtained.

PULSE OXIMETRY

Pulse oximetry has become an invaluable aspect of monitoring in the NICU. This technology is advantageous for the following reasons: It is continuous and noninvasive, it may complement other monitoring techniques, and it can lead in some cases to a reduction in more invasive monitoring or testing. Its widespread introduction has changed the way in which medicine is practiced. In the past several years, long-term data storage has also become possible in most newer pulse oximetry devices, facilitating examination of trends over time. Depending on sampling frequency and manufacturer, pulse oximeters with memory can have data storage capacities of days to weeks. The simplicity of this tool may be deceptive, however, and the assumptions made may not be apparent. It is crucial to understand the underlying principles and potential limitations of this technology.

Principles

Pulse oximetry is an optical method for estimating arterial oxygen saturation (SaO_2) by measuring the color of arterial blood at two or more wavelengths of light.[14] Hemoglobin (Hb) absorbs light differently after it has bound oxygen, reflecting a change in color (Fig. 31-7). The amount of light absorbed by Hb in vitro is dictated by Beer's law:

$$A = \epsilon CL$$

where A = absorbance, ϵ = a constant, C = Hb concentration, and L = optical path length or distance light has traveled through the solution.

Numerous methods for estimating Hb oxygen saturation have been developed, but most rely on measuring total absorbance at two different wavelengths: one in which there is a large difference in absorbance between deoxyhemoglobin (HHb) and oxyhemoglobin (HbO_2), and another above the isosbestic point where HHb and HbO_2 absorbances are not different. Two equations can be constructed and solved simultaneously, with saturation ultimately derived from the percentage of HbO_2 to HHb.[89] The situation in vivo is highly complicated compared with that of the ideal in vitro system. There are absorbers in the body apart from Hb, and light itself is reflected and scattered, making reliable calculations difficult with Beer's law alone.

Early ear oximeters attempted to circumvent these complications by subtracting the light attenuated by bloodless tissue, accomplished by measuring light transmission after vigorously squeezing the pinna, from the total amount of light transmitted through the ear.[129] Hewlett-Packard (Palo Alto, CA) developed the first widely used oximeter, which used a broad spectrum of light, measuring absorbance at eight different wavelengths.[92] This device was highly accurate, but it was cumbersome, expensive, and unsuitable for neonates because of the large size of the ear probe (10 cm × 10 cm).

Development of modern pulse oximetry occurred after variation in earlobe absorbance was noted with each heartbeat, from a minimum during diastole to a maximum during systole.[5] During diastole, the volume of venous and arterial blood is constant, with the sum of diastolic absorbance from tissue and blood forming a baseline. During systole, tissues swell with incoming arterial blood. Subtracting the diastolic baseline from the total noted at systole yields a signal because of arterial blood (Fig. 31-8). This signal is analyzed at two wavelengths, and saturation is determined.

The instrumentation of pulse oximeters is easily understood from this background. Light transmission is accomplished by a probe placed on a well-perfused capillary bed, such as a finger or toe in larger infants, or across a palm or foot in smaller infants. Adhesive-backed bandage material is used for neonatal probes. Two light-emitting diodes (LEDs) generate red (i.e., 660 nm) or near-IR (i.e., 940 nm) light. The LEDs are usually supplied with a chopped current at a high frequency to allow their light to be distinguished from ambient light, which is accomplished in different ways by different manufacturers. A photodiode is opposite the LEDs and detects ambient light and the red and near-IR light, and a current is generated that represents the intensity of light detected at each wavelength. The current passes through an isolation network and is converted to voltage, which is presented to a high pass filter that rejects ambient light. Before presentation to the microprocessor, the signal passes through an A/D converter. Depending on the pulse oximeter model or module, the microprocessor derives the oxygen saturation value (SpO_2), a plethysmogram waveform, and a pulse value calculated from the plethysmographic signal.

Limitations

Many assumptions are made to derive an estimate of SaO_2 noninvasively, but these assumptions can lead to serious errors if they are not met (Box 31-2). Perhaps the most important is the assumption of adequate pulse pressure. Because the technology of pulse oximetry depends on subtraction of a baseline absorbance from that measured at systole, pulse oximetry may be unreliable in low perfusion states. Clinically, infants in septic shock or in significant cardiac failure—infants who most require oxygenation monitoring—may have unreliable or undetectable SpO_2 measurements. Low light transmission may result in a signal too weak to measure adequately. Even with optimal probe placement, this phenomenon may be observed in edematous infants. Skin pigmentation does not seem to have significant effects on SpO_2 accuracy, however.[37]

The accuracy of pulse oximetry is approximately ±3% (when saturation is 80% to 95%),[42] and does not allow for precise estimation of PaO_2 at saturations greater than 95%.[59] Although this fact is important to recognize in many clinical management scenarios, this imprecision may not be as great a factor as previously believed in the approach to preventing retinopathy of prematurity. One report[26] suggested that among infants with very low birthweight, instituting a policy that included vigorously maintaining SpO_2 at less than 95% during the first weeks of life substantially decreased the incidence of retinopathy of prematurity grades 3 to 4 and the need for laser treatment. The problem of pulse oximetry imprecision at higher saturations could theoretically be avoided if SpO_2 is maintained at a lower range, which is more appropriate in this clinical scenario. Nevertheless, the potential inaccuracy of pulse oximetry should still be kept in mind, particularly when setting upper saturation limits.

Inaccuracy is also inherent in the case of poorly saturated patients. In these situations, SpO_2 may be an inaccurate or insensitive reflection of actual SaO_2,[76] or it may appear clinically acceptable owing in part to the presence of high fetal Hb levels in the newborn circulation, but PaO_2 may be unacceptably low. Although fetal Hb does not affect oximeter accuracy itself in any clinically significant way, other Hb forms, such as methemoglobin and carboxyhemoglobin, can significantly affect accuracy of the saturation reading owing to their relative absorbance at the wavelengths used by pulse oximeters.[131] Although this problem is rarely clinically relevant, it can greatly complicate and delay diagnosis if not recognized. In the presence of elevated levels of other Hb forms, erroneous and falsely high SpO_2 readings occur because the pulse oximeter measures these other Hb fractions as HbO_2. Consequently, the displayed SpO_2 is higher than the true patient SaO_2.

BOX 31–2 Clinical Issues That May Affect Pulse Oximetry

- Poor pulse pressure
- Significant hyperoxia
- Severe hypoxia
- Presence of other hemoglobin forms
- Electrical interference
- Optical interference
- Motion

Electrical or optical interference can lead to incorrect saturation estimates by burying the absorbance signal in noise. The signal from an oximeter may be extremely small compared with other signals,[31] and it may be obscured if power sources are not shielded properly. Interference by light sources alone is usually easy to remedy by placing an opaque cover over the pulse oximeter site. Movement has also been a significant source of error or artifact in pulse oximetry, caused by the inability of conventional devices consistently to detect a pulse change and alterations in baseline patient blood volume during motion.[60] This problem can lead to substantial difficulties in optimal management during air or ground transport of critically ill infants. Several companies have now developed devices that are relatively motion resistant with improved monitoring capabilities in low signal-to-noise conditions. Although each manufacturer has a different approach to overcoming motion-related interference, these "next generation" devices have reduced a potentially significant problem.

Potential Solutions

There is no doubt that pulse oximetry is a rapid, noninvasive, and generally reliable monitoring system. Many of the problems encountered in the clinical arena that affect pulse oximetry can be remedied or improved so that consistent readings can be obtained. The assumptions underlying conventional pulse oximetry cannot be altered, however, and, especially in the case of motion, solutions may be challenging.

Several companies have attempted to circumvent the problems presented by motion by designing pulse oximetry systems with complex filtering algorithms. After extensive benchtop and clinical research, Masimo Corporation (Irvine, CA) developed a system using a unique recessed sensor design (low noise optical probe [LNOP]), minimizing (although not eradicating) the effects of venous blood movement during motion, and a software algorithm referred to as the Discrete Saturation Transform (DST) (Fig. 31-9). In this algorithm, a noise reference is built for incoming red and IR signals for all saturations from 1% to 100%. An adaptive filter is used to remove correlated frequencies between the noise signal and incoming red and IR signals, and the remaining output is measured and plotted for all possible saturations. If several peaks are generated, as with motion, the peak considered to be most consistent with arterial pulsation is reported.

This algorithm is different from conventional pulse oximetry in that it calculates SpO_2 without first having to reference the pulse rate. This system was studied in a rabbit model of sepsis and low perfusion and was found to be less prone to signal loss than the traditional pulse oximeter.[70] In adult volunteers in situations of motion and low perfusion, the technology was found to be superior to other traditional or advanced pulse oximeters tested.[11] Studies in the neonatal population indicate CO-oximetry validation of the method, improved sensitivity and specificity, and dramatically improved reliability on transport and during extracorporeal membrane oxygenation (ECMO) therapy compared with traditional pulse oximetry.[48,55,58,66] Masimo has also developed additional proprietary

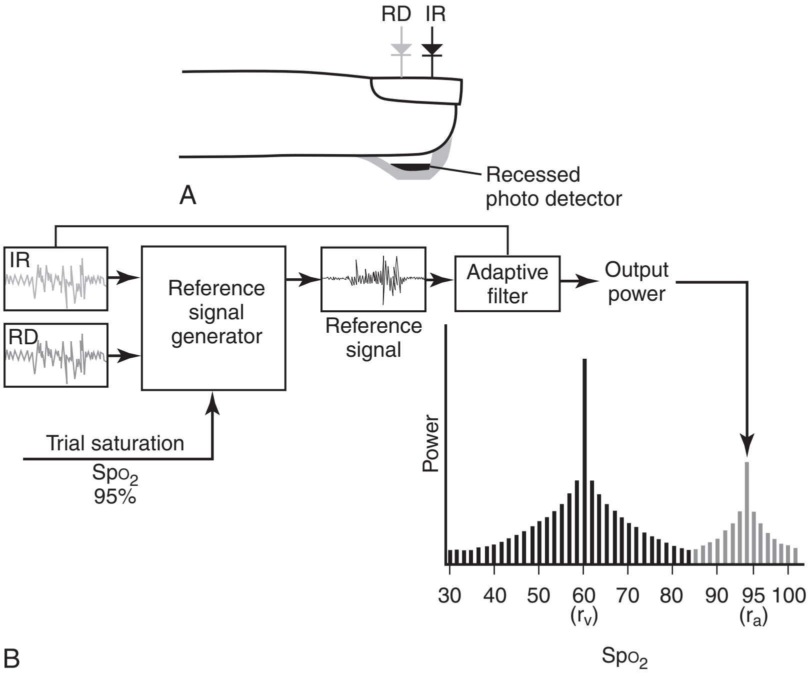

Figure 31–9. A, Low noise optical probe (LNOP) design. B, Schematic of the Discrete Saturation Transform (DST) for pulse oximetry analysis. IR, infrared; r_a, arterial optical density ratio; RD, red; r_v, venous optical density ratio. *(Courtesy of Masimo Corporation, Irvine, CA.)*

algorithms, which work in parallel with DST, and are aimed at ensuring accuracy of output in high noise situations.

More recently, Masimo has developed the Rainbow SET Pulse CO-Oximeter, which integrates their pulse oximetry with technology to measure Hb, oxygen content, carboxyhemoglobin, and methemoglobin noninvasively. A new second generation pulse oximeter called the SET Radical V4 is being tested. Other companies also have developed signal processing algorithms and adaptive filters to attempt to address the problems encountered with motion and false alarms,[104] which are incorporated into newer oximeters including the Nellcor (Pleasanton, CA) OxiMax N-20PA (hand-held)/N-560 (monitor), Philips (U.S. headquarters, Andover, MA) Viridia Rev C1, and Novametrix MARS (Motion Artifact Rejection System) 2001 Oximeter.

As a direct result of these algorithms, manufacturers have integrated improved warning technologies into newer pulse oximeters. These include “Pulse Search” warning on the Nellcor N-395/N-595, and “Signal IQ” warning on Masimo devices. Data validity warning systems are meant to indicate to the clinician that the signal may be of poor quality, and output may be susceptible to error. Preliminary studies in neonates have begun to assess and compare the reliability of these systems,[54,121] but larger investigations are required to determine the positive and negative predictive value of each technology.

Pulse oximetry systems with this type of technology may be more expensive than traditional pulse oximetry systems, specifically as a result of the cost of the probes or sensors. The increased cost may outweigh the potential benefits for many newborn nurseries. A preliminary two-center study of infants suggested that LNOP pulse oximetry probes had a useful life of 9.05 ± 4.4 days compared with 3.9 ± 2.3 days for more conventional oximetry probes.[40] In addition, much of this technology is limited to separate unit systems, and cannot be “retrofitted” into existing monitoring module systems. Masimo has developed partnerships and agreements with many other manufacturers that allow Masimo signal extraction technology to be available in the monitoring devices of other companies. The applicability of next-generation pulse oximeters for routine use in newborn nurseries depends on numerous factors. Nevertheless, in situations in which movement is expected, such as during ground or air transport or transport within a facility, this technology may be beneficial. One promising new approach is to provide automated adjustment of supplemental O_2 that is regulated by targeted pulse oximeter readings.[26a]

CONTINUOUS BLOOD GAS MONITORING

Intravascular sensors or ex vivo point-of-care systems for blood gas analysis offer the benefit of continuous or near-continuous measurements of pH, PaO_2, $PaCO_2$, and in some cases certain electrolytes, without patient blood loss or need to wait for results. These devices have been used and studied in adults for applications such as intraoperative and postoperative monitoring and have been found to provide good agreement with traditional in vitro blood gas measurements.[91,122,134] In addition, retrospective studies have revealed that these types of catheters can be used in term and premature neonates with complication rates consistent with umbilical catheterization alone.[28,98] There are several types of continuous monitoring systems, and each has a slightly different theory of operation.

One such type of monitoring system, of which the Neotrend System (Diametrics Medical, Inc., St. Paul, MN) is representative, can report numerous parameters, including pH, $PaCO_2$, PaO_2, and temperature, owing to a sensor that is placed within a 3.7-Fr umbilical artery catheter (Fig. 31-10). The Neotrend sensor consists of three optical sensors and mirror within a 0.5-mm diameter sheath, and a thermocouple for temperature measurements. The pH sensor uses the principle that phenol red dye changes color reversibly in response to hydrogen ions. Hydrogen ions permeate through a microporous hollow fiber containing the dye, absorption is measured

at 555 nm, and pH is calculated. The $\mathrm{Pa}\textsc{co}_2$ sensor uses this same principle; however, the membrane surrounding the phenol red–bicarbonate solution is surrounded by a gas-permeable, but not an ion-permeable, membrane. The $\mathrm{Pa}\textsc{o}_2$ sensor is based on the principle of fluorescence quenching. An oxygen-sensitive, ruthenium-based dye is immobilized in a gas-permeable complex, and an excitation beam at 460 nm is transmitted. The excitation light is absorbed by the indicator dye, and fluorescent light is emitted. When oxygen is present, the fluorescent light is quenched, allowing for calculation of $\mathrm{Pa}\textsc{o}_2$. A dedicated screen displays results continuously, and data trends are recorded for 10 minutes to 24 hours.

This system has the advantage of allowing for continuous multiparameter assessment of a critically ill newborn, reducing blood sampling, and potentially reducing the chance of infection owing to multiple line access events. At present, a specifically designed, Neotrend-compatible catheter must be used in conjunction with the sensor. A one-time, 30-minute calibration is required before insertion, and an in vivo comparison blood gas analysis is required after catheter insertion. Calibration is recommended occasionally throughout the period of use. Initial studies in neonatal patients revealed bias and precision data that suggest that this type of system could be of potential clinical benefit, although the need for traditionally obtained arterial blood gases would not be completely eliminated.[94]

Another approach to blood gas monitoring has been applied in the VIA-LVM (low volume mode) Monitor (VIA Medical Division of International Biomedical, Inc., Austin, TX). In this system, the monitor is a microprocessor-based instrument that integrates the functions of a volumetric infusion pump with an electrolyte and blood gas parameter measurement system (Fig. 31-11). The sensor set consists of two flow cells. The sensor set is connected to the intravenous cannula and contains ion-selective electrodes to measure pH, Na^+, K^+, and $\mathrm{Pa}\textsc{co}_2$. A Clark electrode and electrical conductance technology are used to measure $\mathrm{Pa}\textsc{o}_2$ and hematocrit. This system is closed-looped, whereby a reversible pump withdraws 1.5 mL of blood from any arterial line to the sensor set, analysis is performed, and the blood is returned to the patient followed by a 0.5-mL postsample flush from an in-line heparinized solution, which is also the calibration fluid. Results are displayed approximately 70 seconds after sampling and are printed. The system has a 40-sample memory so that trends may be noted. An initial 2-point calibration is required, after which 1-point self-calibrations are performed after each sample and every 30 minutes. The sensor set may be changed every 72 hours in accordance with infection control policies.

Studies in adults using this system have reported performance criteria acceptable by the Medicare Clinical Laboratory Improvement Amendments (CLIA) proficiency standards.[8] Results from a multicenter evaluation of this system in the neonatal intensive care population[20] suggest that data obtained from this monitoring system agree with results from laboratory-based analyzers within CLIA limits. A hand-held portable point-of-care device, the i-Stat 1, developed by Abbott Laboratories Point-of-Care Division (Abbott Park, IL), measures blood gases and electrolytes, chemistries, glucose, hematology, and cardiac markers (cTn1), using only two drops of blood.

NEAR-INFRARED SPECTROSCOPY

Near-infrared spectroscopy (NIRS) is a noninvasive optical method to monitor regional tissue oxygenation continuously. In contrast to pulse oximetry, which depends on arterial pulsations, NIRS can effectively detect regional oxygenation during low perfusion states. It has most commonly been used to measure cerebral oxygenation, where near-IR light is transmitted and detected by a probe placed on an infant's forehead. Because near-IR light at different wavelengths is measured, and because HbO_2 and HHb have different absorption spectra, regional tissue oxygen saturation ($\mathrm{rS}\textsc{o}_2$) can be calculated: $\mathrm{rS}\textsc{o}_2 = HbO_2/(HbO_2 + HHb)$.

NIRS was first applied to neonates for monitoring of tissue oxygenation in 1985.[23] Early NIRS devices were prone to movement artifact and were unable to produce reliable absolute values because of the variable light-scattering effect of different body tissues. As a result, the technology was limited by significant interpatient variability and lack of standardized tissue oxygenation parameters across subjects.[127] Newer NIRS technology uses spatially resolved spectroscopy to avoid these problems.

One manufacturer (Somanetics, Corporation, Troy, MI) uses a NIRS probe containing a two-wavelength near-IR light source (700 to 900 nm) and two detectors located at different distances from the light source. Another manufacturer (Hamamatsu, Bridgewater, NJ) measures absorption at three points using the diffusion equation to calculate a tissue oxygenation index. Issues of signal contamination by extracranial tissue layers are less prominent in neonates because of their thinner skull and scalp. rSO_2 or tissue oxygenation index value is measured at a depth of approximately 2.5 to 3 cm (depending on NIRS device manufacturer) beneath the sensor. Assuming a weighted average of 20% arterial, 75% venous, and 5% capillary blood, the rSO_2 reflects a regional balance between oxygen supply and demand similar to a mixed venous oxygen saturation. NIRS is noninvasive, requires minimal caregiver attention when properly positioned, shows good reproducibility in neonates,[90] and provides a continuous signal that is not affected by changes in blood pressure, pulse, or temperature.

NIRS is not without its limitations. Given the depth of signal penetration, placement of the NIRS sensor on a neonate's forehead measures regional cerebral oxygenation of frontal cortex only and not deeper brain structures. Absolute values of rSO_2 may show a significant amount of variability among patients depending on sensor placement. There may be a 10% difference in rSO_2 between left and right cerebral hemispheres, especially during periods of unstable systemic oxygenation.[85] Interpretation of NIRS values must be made in the context of other factors that influence cerebral bloodflow and oxygenation, such as anemia, CO_2 tension, glucose levels, mean arterial blood pressure, metabolic rate, and drug administration. Although absolute NIRS variables are now more reliable to assess cerebral oxygen delivery, cerebral oximetry is still most useful to detect trends from baseline and changes over time in an individual patient.

Interpretation of absolute NIRS measurements has been the subject of ongoing research. Although an absolute value of rSO_2 associated with tissue damage is not standardized, rSO_2 less than 40% during cardiac surgery may be associated with early postoperative neuropsychological dysfunction, a critical reduction in oxygen flux, electroencephalogram changes, and intracellular anaerobic metabolism and depletion of high-energy phosphates, especially when lasting longer than 10 minutes.[64,80,132] Hypoxia studies performed in piglets showed neuronal mitochondrial injury in the hippocampal CA1 zone for cerebral rSO_2 values 30% to 40% and cellular vacuolization and fragmentation for rSO_2 values less than 30%.[68] In addition to rSO_2, NIRS can be used to estimate cerebral blood volume, cerebral bloodflow,[88] and fractional tissue oxygen extraction ($FTOE = [SaO_2 - rSO_2]/SaO_2$). Increased FTOE reflects higher oxygen consumption in relation to oxygen delivery to the brain, whereas decreased FTOE suggests less use of oxygen by brain tissue.[83]

Simultaneous monitoring of regional oxygen saturation in brain and somatic tissue beds may reflect hemodynamic compromise and redistribution of bloodflow earlier than NIRS monitoring of either site alone. A separate somatic NIRS sensor can be placed over the flank region to assess renal oxygenation or over the abdomen to measure mesenteric oxygenation and corresponding splanchnic bloodflow. Although autoregulatory mechanisms normally maintain cerebral oxygenation at fairly constant levels, renal and mesenteric bloodflow are extremely sensitive to cardiac output and sympathetic control. Regional oxygen saturation of renal tissue is typically higher than cerebral saturation by 15% to 20%,[64] but circulatory impairment preferentially reduces somatic saturation before cerebral saturation. The use of two-site NIRS reflects distribution of overall bloodflow, allowing for earlier detection of shock. NIRS has also been correlated with mixed venous oxygenation (SvO_2) and lactate levels.[64,75] Other investigators have found that a ratio less than 0.75 between mesenteric and cerebral oxygenation was predictive of intestinal ischemia in neonates.[44]

Clinical Applications of Near-Infrared Spectroscopy

NIRS use has expanded to include several applications in the NICU setting. Preterm infants, who are at risk for hemodynamic instability, are an ideal population to be studied with cerebral oximetry. One study found a significant correlation between decreased cerebral oxygenation and subsequent development of severe intraventricular hemorrhage by cranial ultrasound.[109] Preterm infants with significant hypotension are also at a higher risk for developing impaired cerebral autoregulation. NIRS has been used to identify preterm infants with impaired cerebral autoregulation who subsequently developed severe intraventricular hemorrhage or periventricular leukomalacia.[120] Cerebral autoregulation can be assessed with NIRS by correlating changes in cerebral oxygen saturation with changes in systemic blood pressure.

NIRS measurements of rSO_2 or Hb difference (HbD) signal provide a good estimate of cerebral bloodflow.[13,83,117] This approximation has been validated in animal studies using the gold standard radioactive microsphere technique[110,120] and confirmed by transcranial Doppler ultrasound as a reliable method to assess for impaired cerebral autoregulation.[13] Specifically, concordance between mean arterial blood pressure and Hb difference (or rSO_2) indicates a pressure passive cerebral circulation and presumed loss of autoregulation.[110,115] The prevalence of pressure passivity has been quantified using a pressure passive index defined as the percentage of 10-minute epochs with significant coherence between mean arterial pressure and Hb difference signals in the low frequency range.[110] A study of pressure passivity in premature infants using NIRS found that cerebral pressure passivity signifying loss of autoregulation occurred in most premature infants with a mean pressure passive index of 20%.[110] Pressure passivity was associated with low gestational age and birthweight, systemic hypotension, and maternal hemodynamic factors.

The relationship between loss of autoregulation and cerebral injury has also been studied with NIRS. Concordant changes between mean arterial pressure and cerebral oxygenation in preterm infants were significantly associated with increased severe intraventricular hemorrhage and periventricular leukomalacia[99,120] and with mortality.[128] Development of a symptomatic patent ductus arteriosus in preterm infants is another common occurrence amenable to monitoring with cerebral oximetry. Decreased rSO_2 values are associated with the presence of a hemodynamically significant patent ductus arteriosus, whereas pharmacologic ductal closure with indomethacin normalizes rSO_2.[84] Correlation of these changes in rSO_2 with long-term neurodevelopmental outcomes is currently under investigation.

Neonates with congenital heart disease at risk for decreased cerebral oxygenation preoperatively or postoperatively could also potentially benefit from NIRS monitoring in the NICU. NIRS has been successfully used to monitor cerebral perfusion in neonates on cardiopulmonary bypass and during cardiac surgery.[4,65] Neonates with transposition of the great arteries and a low preoperative rSO_2 ($<35\%$) had lower developmental quotient scores at 30 to 36 months of age.[117] A greater than 20% decrease in rSO_2 has been associated with the development of seizures, hemiparesis, and adverse neurodevelopmental outcome at 18 months of age in patients undergoing congenital heart surgery.[7,80,118,132]

The cerebral oximeter has been validated further as a tool to measure cerebral venous oxygen saturation and tissue oxygen saturation in patients on venovenous ECMO with a precision of 5%.[102] Correlation of NIRS with long-term outcomes in neonatal ECMO patients remains to be studied. Other infants at risk for significant changes in cerebral oxygenation include neonates with hypoxic-ischemic encephalopathy. After birth asphyxia, infants with adverse neurodevelopmental outcomes had a nearly 50% decrease in FTOE, likely reflecting secondary energy failure.[118] Another study of infants with a history of perinatal asphyxia found that an increased cerebral blood volume[88] or an unusually high rSO_2[118] on the first days of life were associated with adverse neurodevelopmental outcomes at 1 to 2 years of age. The increased cerebral blood volume as measured by NIRS had a sensitivity of 86% for predicting death or disability.[88]

The creation of bedside, noninvasive NIRS functional imaging systems also has led to studies revealing real-time activation of sensorimotor cortex during passive movements in premature infants.[62] Ongoing clinical research with NIRS is likely to reveal other clinical scenarios amenable to monitoring of regional oxygen saturation levels.

VISIBLE LIGHT SPECTROSCOPY

Visible light spectroscopy (VLS) is another optical technology developed for detection of tissue hypoxia and ischemia. VLS, also known as reflectance spectrophotometry, uses visible light to measure Hb oxygen saturation (StO_2) noninvasively in thin volumes of mucosal tissue. A light source emits white light in the visible spectrum with wavelengths of 400 to 625 nm. This light is transmitted to tissues using a fiberoptic probe that does not need to come into direct contact with the mucosal surface. With visible light, shallow penetration of tissues to a superficial depth of about 0.25 mm occurs.[47] Hb from larger blood vessels such as arteries and veins absorbs nearly 95% of the light. The light that passes through capillaries is scattered back to the detector. The light is collected by a detector on the probe and analyzed for the concentration of HHb and HbO_2 through comparison with known reference Hb absorption spectra. With a least-squares fitting algorithm and additional signal processing techniques, StO_2 is calculated: $StO_2 = HbO_2/(HHb + HbO_2)$. Early absorption measurements of HbO_2 and HHb were made at four or fewer wavelengths, but newer VLS instruments such as the T-Stat 303 Tissue Oximeter (Spectros Corp., Portola Valley, CA) analyze a full-absorption spectrum. Reliable measurements can be obtained multiple times per second, allowing for real-time monitoring of StO_2.

Mucosal oxygenation is rapidly affected by hypoxic and ischemic insults. Tissue oxygenation is not significantly affected by vasoconstriction, and in contrast to SaO_2 measured by standard pulse oximetry, StO_2 can be effectively measured under conditions of poor perfusion. During circulatory arrest in infants undergoing cardiac surgery, StO_2 decreased by 10%.[45] Absolute lower values of StO_2 corresponding to tissue injury require further study; however, an anaerobic threshold of 35% has been suggested.[116] StO_2 has also been correlated with measures of central SvO_2 ($r^2 = 0.94$) during cardiopulmonary bypass.[15] Rapid normalization of StO_2 has been shown to reduce the incidence of multiorgan failure after ischemic events.[71]

VLS oximetry has limitations. Changes in StO_2 measured by VLS may be inaccurate during conditions that affect light scattering or the optical path length. The presence of bile, stool, or other optically active materials over mucosal tissues affects measurements.[47] VLS is also designed for evaluation of StO_2 at shallow depths and is best used on thin, capillary-rich mucosal tissues such as the oral mucosa.

Although VLS and NIRS operate on similar optical principles, the difference between visible and NIR light wavelengths results in preferential monitoring of distinct tissues for each type of oximetry. VLS measures small, superficial tissue volumes, whereas NIRS light penetrates to deeper volumes of tissue. VLS is ideal for monitoring gastrointestinal mucosa, and VLS probes have been designed for monitoring of buccal, esophageal, and rectal surfaces.[15] In contrast, NIRS can be used for transcranial monitoring because NIRS light penetrates through skull and thicker skin. NIRS sensors are larger to accommodate detection of wavelengths and may be inappropriate for thin tissue regions. VLS is also more heavily weighted for capillary blood compared with a larger venous and arterial component for NIRS values. Use of VLS and NIRS may provide complementary data.

Clinical applications of VLS include monitoring tissue ischemia in critical care and surgical settings. For more than 25 years, VLS oximetry was primarily used for measuring StO_2 in the gastrointestinal tract during endoscopic procedures for patients with inflammatory bowel disease, stress ulcerations, and portal hypertension.[47] Poor perfusion of gastric mucosa may also occur in conditions of septic shock, with administration of continuous positive airway pressure, and with infusion of vasoactive medications.[45,46,116] These conditions are amenable to monitoring with VLS oximetry. In the perinatal setting, fetal StO_2 has been assessed with VLS oximetry during laser therapy for twin-twin transfusion.[100] Esophageal saturation has been measured with VLS during antegrade cerebral perfusion in neonatal cardiac surgery with hypothermic cardiopulmonary bypass.[61]

Neonatal applications of VLS oximetry may include monitoring patients undergoing ECMO, preterm infants with significant hypotension, and infants with congenital heart disease, or monitoring in other settings of tissue ischemia. Although still predominantly a research tool, current clinical studies may validate the use of VLS oximetry for noninvasive, real-time monitoring of StO_2, particularly in poor perfusion states when traditional pulse oximetry is inadequate.

MONITORING OF OTHER TRACE GASES

End-Tidal Carbon Monoxide Monitoring

Because the degradation of heme by the enzyme heme oxygenase leads to the formation of equimolar amounts of carbon monoxide (CO) and biliverdin, with biliverdin being immediately reduced to bilirubin, the measurement of CO in the exhaled breath of a newborn can be used as an index of heme degradation and bilirubin production in vivo (see Chapter 48). The measurement of end-tidal CO (ETCO) corrected for inhaled CO ($ETCO_c$) is an index of the rate of bilirubin production and may aid the physician with respect to the recognition of hemolysis-associated hyperbilirubinemia, and subsequent selection of appropriate treatments or interventions.

The measurement of ETCO is a convenient, reliable, and well-studied index.[38] Measurements of ETCO have been found to correlate strongly with carboxyhemoglobin levels,[124] which can be affected by endogenous sources (e.g., hemolysis), exogenous sources (e.g., combustion engine exhaust), or both. Breath can be sampled and analyzed continuously in real time using sensitive and rapidly responding spectrophotometers based on near-IR; these are expensive, however, and often not portable. Intermittent sampling of end-tidal breath can be performed after a 20-second breath-hold with Priestley tube-type devices.[93] Alternatively, this breath can be directly exhaled into an instrument with a quick response time for recording the peak (alveolar) CO concentration.

For newborns and patients who cannot control their breathing, automatic sampling devices have been developed for measuring ETCO.[123-125,133] The CO-Stat End Tidal Breath Analyzer (Natus Medical, Inc., San Carlos, CA), a point-of-care device, was developed for measuring $ETCO_c$ and other parameters, such as breath CO concentration uncorrected for ambient CO concentration (ETCO), ambient CO concentration (reflecting inhaled air), end-tidal CO_2, and respiratory rate.[124,125] The electronically controlled device used two gas sensors: an IR CO_2 sensor and an electrochemical CO/hydrogen (H_2) sensor. The CO sensor first determined the average CO concentrations in breath and room air, and then calculated ETCO by an algorithm using the measured CO and CO_2 concentrations. The CO_2 sensor determined the end-tidal CO_2 concentration and quantitated respiratory rate. The device used sidestream sampling continuously to draw a small volume of breath through a single-use, soft, clear polymer (2-mm OD) sampler consisting of a flexible, 5-Fr nasal catheter with a filter cartridge that attaches to the device.[108] A hydrogel strip ("adhesive wings") on the catheter allowed proper catheter placement and insertion (5 to 6 mm into the lower edge of the nostril).

The measurement was made with the subject at rest (sleeping or quiet) with minimal movement. The instrument had a range of 0 to 25 ppm (or μL/L) with a resolution of 0.1 ppm CO. Its accuracy was 0.3 ppm or 10% of the reading (whichever was greater) at 0 to 60 breaths/min. It was insensitive to H_2 concentrations less than 50 ppm. When breath H_2 concentrations were at 50 ppm, a level that significantly interfered with $ETCO_c$ readings, breath sampling was aborted. Several studies validating use of this device on neonates, children, and adults have been conducted.[10,123-125] The device is no longer commercially available, however.

In a large trial conducted at nine centers, Stevenson and colleagues[112] determined that a measurement of $ETCO_c$ taken at 30 ± 6 hours of age alone did not improve the predictive ability of the hours of age-specific total serum/plasma bilirubin level. $ETCO_c$ in combination with total serum/plasma bilirubin measurement obtained at the same time can be used, however, to differentiate between infants with hemolysis (i.e., increased bilirubin production) and infants with decreased elimination (i.e., hepatic defects in bilirubin conjugation ability). The use of $ETCO_c$ testing is included in a 2004 American Academy of Pediatrics Clinical Practice Guideline[2] (see Chapter 48). The article by Kuzniewicz and Newman[81] emphasizes the association of hemolysis with poor neurodevelopmental outcome, making the detection of hemolysis by $ETCO_c$ a desirable technique in clinical practice.

Many other trace volatile molecules exist in breath and can be measured using various techniques. Some newer techniques are optical in nature (e.g., high precision broadband frequency comb spectroscopy).[12,32,33] Such approaches may yield tools for diagnosing metabolic disorders or monitoring therapies in real time.

FUTURE TECHNOLOGIES

Combining the technologies of microfluidics and nanofluidics and optics may provide new approaches to the early, bedside detection of sepsis through cell sorting and optical tagging of pathogens.[72,73] Prototypes of such technology already exist and could revolutionize the practice of neonatology with respect to more targeted approaches to the treatment of sepsis.

CHAPTER 32

Anesthesia in the Neonate

John E. Stork

In 2010, the provision of anesthesia for all surgical procedures is the standard of care in neonates. Sedation and analgesia for nonsurgical, but noxious procedures is also increasingly common. Beginning with landmark studies by Anand and colleagues,[1,2] it has been shown that surgery causes a humoral stress response that leads to increased complications and mortality. This response is diminished by adequate anesthesia (Fig. 32-1; Table 32-1), resulting in improved surgical outcomes.

Beyond this purely physiologic reason, it is generally accepted that neonates are capable of sensing pain, and that such pain experiences may lead to exaggerated responses to later painful stimuli.[66] Lack of consciousness or memory has been previously used to justify the use of the "Liverpool technique" (i.e., nitrous oxide and curare) in neonatal anesthesia. Adults generally have no memories before 3 to 4 years of age (termed *infantile amnesia*). There is evidence, however, that neonates do possess consciousness and a sense of self, and can form at least implicit memories, that is, changes in behavior based on prior experience that do not require intentional recall.[12] Neonatal anesthesia, in addition to abolishing the humoral stress response, should also inhibit consciousness and prevent the development of memories, as discussed in a review by Davidson.[12] These are the same goals of anesthesia in adult patients; nonetheless, neonatal anesthesia requires different skills, knowledge, and care.

The differences between adults and children are most profound in neonates, particularly premature infants. Advances in neonatology and the almost routine survival of infants weighing 1000 g have led to new challenges for pediatric anesthesiology. Successful anesthetic management in a neonate requires meticulous attention to detail and a thorough understanding of neonatal physiology and development, pharmacology, and pathophysiology. The neonatal period is characterized by immaturity of organ systems, homeostasis, and metabolic pathways. It is a time of major developmental changes, and the effects of anesthesia on that development are not well characterized. Concerns have arisen that many common anesthetic agents may have adverse effects on the developing brain, leading to a new initiative by the U.S. Food and Drug Administration (FDA) to study these risks.[44]

Personnel, equipment, and the operating room environment need to be specifically adapted for neonates. Anesthesia-related morbidity is decreased in children anesthetized by pediatric anesthesiologists compared with children cared for by nonpediatric anesthesiologists.[27] Monitors, anesthesia delivery systems, mechanical ventilators, and environmental controls all need to be appropriate for use with neonates.

It is important to emphasize the perioperative nature of anesthetic management. Anesthesia care does not start and end at the door to the operative suite, and this is as critical in neonates as in older children and adults. Preoperative condition and management affect intraoperative care. Transport to the operating room can be one of the most critical aspects of an operation in a premature neonate. The postoperative period requires close monitoring and management of ventilation, fluid balance, and an environment tailored to the special needs of neonates. Assessment and control of postoperative pain requires methods and tools specific to neonates.

Knowledge of the anatomic and physiologic differences among neonates, children, and adults is critical to careful anesthetic administration and management. Maturity of organ systems and metabolic processes varies significantly not only between adults and neonates, but also between preterm and term neonates.

ANESTHESIA, NEONATAL PHYSIOLOGY, AND SPECIFIC CONCERNS

Transition Phase and Persistent Pulmonary Hypertension of the Neonate

In utero, the pulmonary circulation is a high resistance circuit so that the lungs receive little bloodflow, and oxygenation is a placental function. At birth, approximately 35 mL of amniotic fluid is expelled from the lungs, the lungs reexpand, and respiration begins. The lungs are initially very stiff (compliance very low), and the first breath may require negative forces of 70 cm H_2O or more. Pulmonary vascular resistance (PVR) decreases rapidly with lung distention, and oxygenation and pulmonary bloodflow and cardiac output increase. The increase in pulmonary bloodflow coupled with decreased venous return from the inferior vena cava with

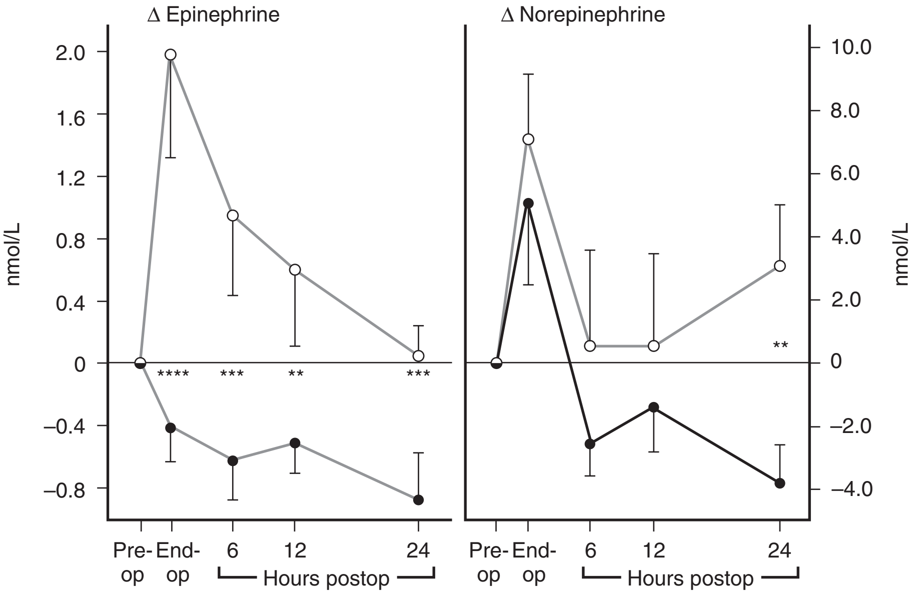

Figure 32–1. Change(Δ) from baseline of epinephrine and norepinephrine in nanomoles per liter (nmol/L) before surgery to the end of the operation and for the first 24 hours thereafter. The two groups reflect nitrous oxide–fentanyl anesthesia (*closed circles*) and nitrous oxide anesthesia (*open circles*). In the patients given fentanyl, there was no increase in epinephrine or norepinephrine, not only during surgery, but also for the first 24 hours after surgery, indicating a significantly blunted stress response.

TABLE 32–1 Perioperative Complications

Complication	Control	Fentanyl
Frequent bradycardia	4	1
Hypotension, poor circulation	4	0
Glycosuria	1	0
Acidosis	2	0
Increased ventilatory requirements	4	1
Intraventricular hemorrhage	2	0
Total complications	*17*	*2*

From Anand KJ et al: Randomised trial of fentanyl anaesthesia in preterm babies undergoing surgery: effects on the stress response, *Lancet* 1:62, 1987.

clamping of the placenta causes left atrial pressure to exceed right arterial pressure, resulting in closure of the foramen ovale. The ductus arteriosus closes between 1 and 15 hours after birth.

Although PVR decreases, the pulmonary arterioles possess abundant smooth muscle, and the pulmonary vascular bed remains very reactive. In this setting, hypoxia, hypercarbia, or acidosis can cause a sudden increase in PVR and a return to a fetal circulatory pattern, a condition known as persistent fetal circulation or persistent pulmonary hypertension of the neonate (PPHN). PPHN is an acute, life-threatening condition, as shunt fraction increases to 70% to 80%, and profound cyanosis results. Many factors during anesthesia can affect this transitional state. Anesthetic agents can markedly diminish systemic vascular resistance (SVR), resulting in right-to-left shunt. Hypoxia or hypercarbia and acidosis from inadequate ventilation can increase PVR, with similar effects on shunt.

Respiratory Physiology: Apnea, Central Control of Ventilation, and Respiratory Distress Syndrome

Anesthetic agents are respiratory depressants. Central regulation of breathing is obtunded under anesthesia, with a significant decrease in the ventilatory response to increased carbon dioxide (CO_2). Compared with older children and adults, in neonates lung volume and functional residual capacity (FRC) as a percentage of body size are much less. Alveolar ventilation per unit lung volume is very high because the neonate's metabolic rate is about twice that of an adult. Most of this alveolar ventilation is provided by a rapid respiratory rate of 35 to 40 breaths/min because tidal volume is limited owing to the structure of the chest wall.

One consequence of the reduced FRC and high metabolic rate in a neonate is a diminished reserve. Changes in the fraction of inspired oxygen (FIO_2) are rapidly seen as changes in PO_2, and the neonate quickly desaturates if ventilation is interrupted. This situation limits time for intubation, and airway management can be difficult. The high alveolar ventilation also accounts for a very rapid uptake of inhalational anesthetic agents, especially in premature infants, making it easy to overdose with these agents. Closing volume, which is the lung volume at which smaller airways tend to collapse, is very close to FRC in neonates. It is well known that anesthesia causes decreases in FRC.[26] In a neonate, this low closing volume can result in airway closure at end expiration, with resultant atelectasis, ventilation/perfusion mismatch, and increased intrapulmonary shunting.

An awake infant uses laryngeal braking resulting in an auto-positive end-expiratory pressure (auto-PEEP) to maintain FRC, but laryngeal braking is diminished by anesthesia. In a premature neonate, alveoli are immature and thick-walled and saccular. Surfactant production begins at 23 to

24 weeks' gestation, but it may remain inadequate until 36 weeks' gestational age; because of this, lung volumes and compliance are decreased further in very premature infants. Although the lung is less compliant in an infant than in an older child, the chest wall in an infant is very compliant. This combination results in increased work of breathing. Because resistance to airflow is inversely proportional to the fourth power of the radius of the airway, the work of breathing is increased further in neonates, particularly small premature infants.

Changes in airway resistance are also common during anesthesia, often resulting from small endotracheal tubes and equipment factors such as inspiratory and expiratory valves in the breathing circuit. Kinking of the endotracheal tube or the presence of secretions also can adversely affect resistance. Respiratory failure from fatigue can occur easily. Most neonates require controlled positive pressure ventilation during operative procedures because of the low FRC, increased closing volume, and increased work, along with changes induced by anesthetics. Infants already being ventilated require some increase in their ventilator settings after induction of anesthesia, and most infants require increased postoperative ventilatory support.

Tracheomalacia is common in premature infants, and if low in the airway, it may not be obviated by intubation. Bronchomalacia may result in airway collapse on expiration. Continuous positive airway pressure (CPAP) or PEEP increases FRC and decreases closing volume and helps to stent open the airway during anesthesia. Slower respiratory rates should be used with positive pressure ventilation to allow time for passive exhalation and to prevent air trapping. The premature lung is very susceptible to barotrauma and oxygen toxicity. Pneumothorax and interstitial emphysema may develop if high peak inspiratory pressures are used.

Periodic breathing with intermittent apneic spells is common in neonates up to 3 months of age. Small premature infants have a biphasic ventilatory response to hypoxia, with an initial increase in ventilation, followed by a progressive decrease and apnea. The ventilatory response to CO_2 is decreased in premature infants and, as noted, is decreased further by anesthesia. Postoperative apneic spells are common in premature infants, although incidence decreases with advancing postconceptional age. These episodes can be secondary to the immature respiratory control system (central), a floppy airway (obstructive), or both (mixed or combined).

Airway Anatomy

Airway anatomy in infants differs from the anatomy in older children. The infant's head is much larger compared with body size than that of older children, although the infant's neck is short. The infant's tongue is large, but the larynx is higher and anterior, with the cords located at C4 in the infant compared with C5 or C6 in an adult. The epiglottis of the infant is soft and folded. The neonate's larynx has commonly been described as conical, with the narrowest point in the subglottic area at the cricoid ring, based on an often-quoted article by Eckenhoff.[17] Eckenhoff's description was apparently based on earlier measurements from plaster castings of a few cadaveric larynxes, and by his own admission, may not apply to living infants.[5,49]

Two more recent articles revisit this anatomy, using the more modern techniques of magnetic resonance imaging (MRI)[37] and video-bronchoscopic imaging.[11] Based on these studies, the larynx is cylindrical, although not round in cross section, but rather elliptical, with the anteroposterior dimension slightly greater. A tight-fitting, round endotracheal tube might compress the lateral laryngeal mucosa; subglottic stenosis remains a common complication, especially with longer term intubation. Although uncuffed endotracheal tubes previously were used in neonates and children, use of new cuffed tubes, composed of very thin, low pressure cuffs and thin walls, is more feasible in at least some infants—an uncuffed tube is still required in the smallest neonates. A cuffed tube can be sized smaller because the cuff prevents leakage and could decrease the incidence of subglottic stenosis, rather than increase it, as previously believed. Laryngeal and tracheal trauma is important because even modest airway edema can be serious. At the cricoid ring, 1 mm of edema results in a 60% reduction in the cross-sectional area of the airway, causing increased airway resistance and increased work of breathing. Laryngomalacia is also common in premature infants and can result in obstruction.

Cardiac Physiology and Patent Ductus Arteriosus

Transitional cardiac changes were discussed earlier. Immediately after birth, with an open ductus arteriosus, most of the cardiac output is from the left ventricle, and left ventricular end-diastolic volume is very high. Consequently, the neonatal heart functions at the high end of the Starling curve. As PVR decreases, output from the two ventricles becomes balanced at 150 to 200 mL/kg per minute. Heart rate is rapid at 130 to 160 beats/min. Because end-diastolic volumes are already high, the infant heart is unable to increase stroke volume to a significant degree, and increases in cardiac output depend entirely on increases in heart rate. Baseline blood pressure is lower in infants than in older children, particularly in preterm infants; because cardiac output is increased, this is due to a low SVR.

Almost all anesthetic agents have significant effects on the cardiovascular system. Inhalational agents tend to be cardiovascular depressants, and they can result in decreased myocardial contractility with bradycardia and subsequent decreased cardiac output. Most anesthetic agents cause decreased autonomic tone and peripheral vasodilation, decreasing afterload and preload. Because baroreceptor reflexes also are blunted by anesthesia, these decreases may make it impossible for the infant to compensate for preexisting volume contraction or volume losses during anesthesia. In a sick neonate, inotropic support may be necessary, and almost all infants require some degree of volume loading during anesthesia. This belief may be at odds with contemporary thoughts on respiratory management, which emphasize diuresis, and volume therapy needs to be carefully balanced to support tissue perfusion, urine output, and metabolic needs.

Patent ductus arteriosus is common in preterm neonates, especially if the neonate is hypoxic, and can result in pulmonary overcirculation and congestive heart failure. The patent ductus arteriosus may close spontaneously. Medical therapy with nonsteroidal anti-inflammatory drugs is sometimes successful. Ducts commonly require surgical ligation.

Fetal Hemoglobin

The infant has approximately 80% fetal hemoglobin (hemoglobin F) at birth. Hemoglobin F has a P50 (partial pressure of oxygen at which hemoglobin is 50% saturated) of 20 mm Hg compared with a P50 of 27 mm Hg for hemoglobin A, which means that hemoglobin F has a higher affinity for oxygen, and that the hemoglobin dissociation curve is shifted to the left. In utero, this hemoglobin dissociation curve favors transport of oxygen from the maternal to the fetal circulation. Put another way, for any given oxygen saturation, the infant has a lower PO_2. Unloading of oxygen at the tissue level also is diminished, although this is compensated for by an increased hemoglobin level of approximately 17.5 g/dL at birth. The decreased unloading can result in tissue hypoxia, however, if PO_2, hemoglobin, or cardiac output decreases during surgery, with secondary development of metabolic acidosis. The hemoglobin increases slightly just after birth, then decreases progressively to a level of 9.5 to 11 g/dL by 7 to 9 weeks of life, owing to decreased red blood cell life span, increasing blood volume, and immature hematopoiesis. Hemoglobin F synthesis begins to decrease after 35 weeks' gestation, and hemoglobin F is completely replaced by hemoglobin A by 8 to 12 weeks of life, paralleling the decrease in hemoglobin and helping to maintain tissue oxygenation.

Renal Physiology

Nephronogenesis is complete at 34 weeks' gestation, and the term neonate has as many nephrons as an adult, although they are immature, with a glomerular filtration rate (GFR) approximately 30% of the adult's GFR. With increasing cardiac output and decreasing renal vascular resistance, renal bloodflow and GFR increase rapidly over the first few weeks of life, and reach adult levels by about 1 year of life. The diminished function over the first year is well balanced to the infant's needs because much of the neonate's solute load is incorporated into body growth, and excretory load is smaller.

Several aspects of renal physiology are pertinent to anesthesia care. First, the neonatal kidney has only limited concentrating ability, apparently owing to a diminished osmotic gradient in the renal interstitium, whereas antidiuretic hormone secretion and activity are normal. Coupled with an increased insensible loss owing to a "thin" skin and increased ratio of surface area to volume, the limited concentrating ability of the kidney implies a tendency to become water depleted if intake or administration is inadequate. The neonatal kidney also is unable to excrete dilute urine efficiently and cannot handle a large free water load. In addition, primarily owing to a short, immature proximal tubule, infants are obligate sodium wasters. There is a tendency toward hyponatremia, especially if too much free water is administered during surgery, which can easily happen with continuous infusions from invasive pressure transducers, especially if adult transducers are used. Because of the lower GFR, the neonate also cannot handle a large sodium load and can easily develop volume overload and congestive heart failure. One final aspect concerns acid-base status: The neonatal kidney wastes small amounts of bicarbonate, owing to an immature proximal tubule; infants are born with a mild proximal renal tubular acidosis, with serum bicarbonate of approximately 20 mmol/L. All these changes are greater in preterm infants, particularly before nephronogenesis is complete at 34 weeks.

Temperature Regulation

Given a large surface area, small body volume, and minimal insulation, neonates are extremely prone to heat loss. Any degree of cold stress is detrimental and increases metabolic demands in the neonate. Infants are unable to shiver effectively, and cold stress causes catecholamine release, which stimulates nonshivering thermogenesis by brown fat. The increased catechols can be detrimental, causing increased peripheral vascular resistance and SVR, increased cardiac stress, and increased oxygen consumption. Anesthesia blunts thermoregulatory sensitivity[7] and interferes with nonshivering thermogenesis and brown fat metabolism.[16] Anesthesia also increases heat loss by inducing cutaneous vasodilation. At all times, including during transport and in the operating room, the infant must be subjected to a neutral thermal environment. An environment that is too warm can be equally detrimental. Core temperature must be carefully monitored at all times in the operating room.

Carbohydrate Metabolism

Whole-body glucose demand corrected for body mass in neonates can be twice that in adults. Carbohydrate reserves, primarily hepatic glycogen, in a normal newborn are relatively low, and even lower in an infant with low birthweight. Hypoglycemia can readily occur if the infant is deprived of a glucose source. Even transient hypoglycemia has been associated with neurologic injury in neonates.[33] In contrast to adults, where hyperglycemia seems to potentiate brain damage during global and focal ischemia,[59] hyperglycemia in neonates may provide some protection from ischemic damage.[15,39] Generally, intravenous glucose (10% dextrose) or intravenous hyperalimentation should be continued intraoperatively, especially in infants with low birthweight without adequate glycogen or fat stores. Nonetheless, hyperglycemia can also be a problem in the perioperative period. Insulin response is deficient in preterm infants, and high catecholamines owing to illness or intraoperative stress can result in hyperglycemia. Careful monitoring of serum glucose is often indicated.

Oxygen Therapy and Retinopathy of Prematurity and Chronic Lung Disease

Hypoxia is a common pathologic condition in neonates because of the incidence of lung disease; congenital heart disease and disordered transition are other frequent causes. Tissue hypoxia, or oxygen delivery to the tissues inadequate to sustain oxidative metabolism, is harmful, with well-known pathologic sequelae. There is at present no good method for reliably detecting tissue hypoxia, particularly in a real-time manner. Oxygen therapy is widely used, particularly during anesthesia, to avoid hypoxia. Until more recently, oxygen has generally been given in excess in the operating room, almost universally resulting in hyperoxemia. Hyperoxemia is always an iatrogenic condition, and there is increasing evidence that it is causally associated with multiple pathologic conditions in neonates, and should be strenuously avoided.[42,61]

Oxygen is a highly reactive molecule, and free radical formation by oxygen is well known. Reperfusion injury, which refers to damage resulting from free radical formation on reoxygenation after a period of hypoxia, is well established. Retinopathy of prematurity is the most widely known complication of hyperoxia, but there is increasing evidence that oxygen may play a role in chronic lung disease, neurologic impairment, and other pathologic conditions. For retinopathy of prematurity, even a brief hyperoxic period, such as during an anesthetic procedure, may be detrimental.[6] There is also some evidence that wide fluctuations in oxygenation, as often experienced during anesthesia, may be damaging.

Monitoring of oxygenation during operative procedures is problematic. Continuous pulse oximetry is the standard of care and has contributed to the safety of anesthesia by avoidance of hypoxia. The pulse oximeter is not as helpful for detection of hyperoxia. At hemoglobin saturations greater than 95%, most infants are hyperoxic; this is altered further by varying amounts of fetal hemoglobin. Maintenance of saturations greater than 95% is almost universal in most operating rooms, but is probably not the best course for neonates. It has been suggested that for ongoing management of neonates in the neonatal intensive care unit (NICU), oxygen saturation targets of 85% to 93% should be used.[20] Similarly, it has become common practice to use blended oxygen levels of 30% to 40% during initial resuscitation. It seems reasonable that F_{IO_2} during operative procedures should be kept as low as possible, as long as saturation is 90% or greater, at least as an initial target. Many neonates can be managed intraoperatively on room air. Further consideration should probably be given to the universal practice of using 100% oxygen during induction and emergence from anesthesia, although this is more problematic because hypoxia should also be avoided, and desaturation during induction and intubation is frequent. This possibility further underscores the need for experienced personnel during induction and intubation of neonates.

Anesthetics and Neurodevelopment

The apparent ability of most anesthetic agents to cause programmed cell death, or apoptosis, in the developing brain and the potential impact on the clinical practice of pediatric anesthesiology are at present a major controversy. First described by Ikonomidou and colleagues in 1999,[28] it has been well established that exposure to agents that either activate γ-aminobutyric acid (GABA) receptors or block *N*-methyl-D-aspartate (NMDA) receptors during peak neural development cause widespread apoptosis in the brains of several species, including rats, mice, and primates. These agents encompass most anesthetics, including isoflurane, sevoflurane, propofol, ketamine, midazolam, barbiturates, and etomidate, and agents potentially abused by pregnant women, such as ethanol. Apoptosis, as contrasted with pathologic cell death, such as seen in ischemia, is an important component of neural development, under the control of neural growth factors and specific enzymes. In addition to the pathologic changes, studies have shown behavioral and learning abnormalities in animals exposed to anesthetics as neonates.

Evidence of these changes in humans, and, even more importantly, evidence of clinical significance at present do not exist. There have been limited studies in humans. Wilder and coworkers[71] reported evidence of increased learning disabilities in a birth cohort exposed to at least two episodes of anesthesia as neonates, but not a single occurrence. In a retrospective pilot study of children who underwent urologic surgery at a young age, Kalkman and associates[31] showed increased abnormal behaviors in children who underwent surgery at less than 24 months of age, although statistical significance was not reached. This is an area of intense interest and investigation, including a special article from the FDA[48] and a multicenter FDA initiative to study these concerns.

An extensive review of the literature is beyond the scope of this chapter. In the last several years, there have been at least 15 reviews and editorials in major journals on this topic.* There is also ongoing investigation into potential molecular mechanisms and modes of action, which, if clinically significant, may lead to the development of protective mechanisms, or other strategies. The current controversy can perhaps be summarized in several points, as follows:

1. Exposure to anesthetic agents, at clinically appropriate doses, at the peak of synaptogenesis can cause widespread neuroapoptosis in several species of animals, including primates. A clinically appropriate dose is the minimum necessary to induce anesthesia in the species. In some species, and with some agents, this dose also results in significant mortality, increasing the difficulty of interpreting the significance.
2. Synaptogenesis in rats occurs postnatally over the first 2 weeks of life. An analogous period in humans would range from the third trimester of pregnancy through the first 3 years of life. Whether the child might be susceptible to anesthetic toxicity during this entire period is unknown. Other studies looking specifically at neurodevelopment suggest that a postnatal 7-day-old rat more closely corresponds to the human fetus between 17 and 22 weeks of gestation. Elucidation of the critical period is of prime importance in anesthetic management.[40]
3. The animal studies of apoptosis involve anesthesia without surgery. There is some indication that the presence of surgical stress may alter the response to anesthetics.
4. Abnormal behaviors and learning have also been shown in animal studies after anesthetic exposure.
5. Initial extremely limited studies of children after anesthetic exposure as infants are suggestive, but difficult to interpret. It is impossible to separate the effects of anesthesia from the effects of surgery; the fact that in Wilder and colleagues study[71] an effect was seen only with multiple anesthetics might be related to dose, but could be related to other confounding effects, such as more severe illness.
6. The effects under examination are subtle, and difficult to categorize and measure. The effects of fetal ethanol exposure

---

were first elucidated because of marked craniofacial abnormalities, rather than more subtle developmental problems.

7. As has been proposed, the careful multicenter FDA initiative may be needed to determine the clinical impact of the problem.

Should these data cause any change in current clinical practice? No one can question the overwhelming benefit of anesthesia in the setting where a surgical procedure, or any noxious procedure with significant stress, is required. The detrimental effects of surgical stress have been well shown. Similarly, the benefits of early repair of some surgical problems, such as tetralogy of Fallot or neonatal hernia with risk of incarceration, have been shown, although such repair may lead to anesthesia at a younger, and potentially more susceptible, age.

A reasonable compromise can be suggested. First, the benefits versus the risk of delay in surgical procedures, particularly if performed in premature infants, should be carefully considered. Similar concerns could be raised in older children if the procedure is elective. Second, it seems reasonable to perform a "simple" anesthetic. There is virtually no extensive experience with many anesthetic agents in neonates. This lack of extensive experience is not unusual in neonates or pediatrics in general, but may be of increased importance given the small therapeutic margin of most anesthetics. There would seem to be little utility in the combination of agents, such as midazolam, propofol, and isoflurane, when a single agent could be as easily used. Whether the use of multiple agents could decrease the required dose of each, and whether this would be beneficial is impossible to answer.

One preference is to use a predominant narcotic technique in premature infants who may be most at risk, when appropriate. Fentanyl has little, if any, activity as either an NMDA antagonist or GABA agonist. It is well tolerated hemodynamically, and effective at preventing the surgical stress reaction. This particular technique may prevent extubation, but in this generally ill population, this is not usually a consideration. The possibility of recall with a pure narcotic technique can be raised, but with a dose adequate to prevent the stress response, this may not be important.

CONDUCT OF AN ANESTHETIC

Preoperative Evaluation and Preparation

The preoperative evaluation should encompass the infant's physical condition, including significant illness, the degree of transition from fetal to newborn physiology, maturity, and the presence of any congenital anomalies. Particular attention should be paid to cardiorespiratory status, required ventilatory or hemodynamic support, blood chemistries, and nutritional support. The course of pregnancy, labor, and delivery and a full maternal history are important details. As is the case with older children, a family history of anesthetic difficulties may be important. Maternal diseases such as diabetes, systemic lupus erythematosus, and preeclampsia have implications for the neonate. Congenital infections, oligohydramnios, intrauterine growth restriction, and maternal drug and alcohol use are also important considerations.

Gestational age, birthweight, and postnatal age affect anesthetic care. Birthweight does not accurately reflect maturity, unless the infant is appropriate for gestational age, which is defined as being within 2 standard deviations of the mean for gestational age. Infants who are small for gestational age are more mature than their birthweight would indicate. Infants who are large for gestational age are often children of diabetic mothers, and they are at increased risk of hypoglycemia in the first 48 hours after birth. Newborns are characterized by birthweight as low birthweight (≤2.5 kg), very low birthweight (≤1.5 kg), and extremely low birthweight (<1000 g). Term is gestational age of 37 to 42 weeks, preterm is younger than 37 weeks, and post-term is older than 42 weeks.

A history of birth asphyxia or neonatal resuscitation and Apgar scores are important. History should include complete details of the present illness and treatment. Medications and administration times, details of vascular access, and respiratory parameters including ventilator type and settings all are crucial details, especially in sicker infants. Infants on high-frequency oscillatory ventilation may need to be switched to conventional ventilation and observed for several hours to facilitate movement to an operating room. If the infant is on some other modality, such as inhaled nitric oxide or extracorporeal membrane oxygenation, arrangements may also need to be made, and transport to the operating room would require more resources and assistance.

The time of the last oral feed should be ascertained, especially in elective surgery in healthier infants. Attenuation of airway reflexes with induction of anesthesia places the infant at risk of aspiration of acidic gastric contents, which can lead to serious inflammatory pneumonitis. NPO (*nil per os* [nothing by mouth]) guidelines are summarized in Table 32-2[19,57]; these guidelines are more liberal for newborns than adults. Studies suggest that a safe NPO time after a formula feed might be 4 hours.[9] This shorter length of time partially reflects more rapid gastric emptying, although in an infant, dehydration occurs much more quickly than in an adult, and this is a concern in an infant without an intravenous line. As in adults, gastric emptying is delayed with stress, anxiety, and illness. Infants with diseases such as pyloric stenosis, duodenal atresia, malrotation, or other obstructive lesions are NPO before surgery, and they need an intravenous line to maintain appropriate hydration. Despite the NPO status, there usually are significant gastric contents, and rapid-sequence or awake intubation is required. Emptying the stomach via nasogastric drainage is undependable and usually inadequate. Nasogastric feeds in intubated infants also should be discontinued at an appropriate time because the infant may need to be reintubated during surgery, and a full stomach would increase the risk for aspiration.

Physical examination includes vital signs, including temperature. Volume status needs to be carefully assessed

because major shifts can occur easily during surgery. Many infants requiring surgery are ill. Infants with congenital anomalies often have multiple defects, which may have an impact on anesthetic care. Often a group of defects suggests a well-recognized and characterized syndrome. Common syndromes with their anesthetic implications are listed in Table 32-3 (this list is incomplete).

Difficult intubation is a common problem in infants with congenital defects, and the airway needs to be carefully assessed. Because of the tendency for rapid oxygen desaturation in infants, difficulties with intubation can be extremely serious. In infants who are already intubated, tube size and position should be evaluated. The pressure at which a leak occurs around the tube should be documented. Nurses should be questioned about the quantity and consistency of secretions and need for frequent suctioning. The small tubes required in premature infants can easily be blocked by tenacious secretions and are easily dislodged. If there is any question about adequacy of intubation, the infant should be electively reintubated before surgery; emergently replacing an endotracheal tube under the drapes after beginning an operation is not a benign procedure.

A complete clinical physical examination should be performed, with particular attention paid to cardiorespiratory status. Laboratory studies and x-ray films need to be reviewed, if applicable. Hemoglobin level usually should be greater than 13 g/dL to ensure adequate oxygen delivery to the tissues, given the decreased unloading at the tissue level by fetal hemoglobin. Metabolic acidosis should be corrected, preferably by reversal of the cause of the acidosis. Electrolyte levels help to guide fluid management; hypocalcemia should be corrected. For most operations, it is important to check that blood for transfusion is available; for major procedures, fresh frozen plasma and platelets for transfusion also may be required.

Several specific areas should be explored by the anesthesiologist. As previously discussed, the pulmonary circulation in a neonate is hyperreactive, and in a near-term infant, lung disease, asphyxia, and surgical stress can initiate episodes of pulmonary hypertension, resulting in decreased cardiac output and oxygen desaturation. Any history of such spells requires increased vigilance to avoid hypoxia, hypercarbia, and acidosis, which tend to increase pulmonary resistance. Bronchopulmonary dysplasia is a common chronic lung disease of premature infants. Infants with bronchopulmonary dysplasia are susceptible to excessive pulmonary vasoconstriction in response to hypoxia, hypothermia, or acidosis. Because of their chronic lung disease, these infants may have some degree of cor pulmonale, and decreases in myocardial function related to anesthetics may result in acute right heart failure. Other problems in bronchopulmonary dysplasia include airway hyperreactivity, increased airway secretions, electrolyte abnormalities because of diuretic therapy, and frequently tracheomalacia.[46,63]

Congenital anomalies of the heart also must be carefully evaluated. Right-to-left shunts affect the oxygenation of the infant, whereas left-to-right shunts typically result in volume overload. The infant should be carefully evaluated for signs of congestive heart failure, such as hepatic congestion, enlarged heart, and edema. The presence of single ventricle physiology is particularly important because the anesthesiologist needs to take great care to maintain balance between the pulmonary and systemic circulations. High inspired oxygen concentration in these infants results in pulmonary vasodilation and pulmonary overcirculation at the expense of systemic circulation, with consequent acidosis. Particular attention should be paid to ventilation; in some cases, increased inspired CO_2 may be beneficial.[63] Abnormal pulses on physical examination may indicate coarctation of the aorta. Antibiotic prophylaxis for endocarditis is also often important in neonates with congenital heart disease. Intrinsic arrhythmias are unusual in a neonate, although congenital heart block may occur in infants of mothers with systemic lupus erythematosus.

Neurologic function also should be carefully assessed. Hemodynamic changes during surgery may affect cerebral bloodflow. A history of seizures should increase the anesthesiologist's level of suspicion for intraoperative seizure if there are unexplained tachycardias or blood pressure elevations. The presence of intraventricular hemorrhage requires increased care with hemodynamic stability and is a contraindication to procedures requiring anticoagulation. A history of hydrocephalus mandates avoidance of factors that increase intracranial pressure.

Transport

Transport of a premature infant may be as great a risk as the surgery itself. Dedicated transport incubators, with a built-in ventilator, air and oxygen supplies, and a blender, are now available and should be used if possible. If this equipment is unavailable, extra care must be taken. In addition to the inherent risks involved in the transport of a potentially unstable patient, premature neonates are particularly susceptible to cold stress. Heat loss during transport must be addressed because the hospital corridors are rarely neutral thermal environments. If the infant is in an incubator, the incubator should be used for transport because heat is retained even when it is unplugged. An infant on an open radiant warmer should be covered, including the head. In some institutions, plastic wrap is used to retain heat and to reduce evaporative losses. Disposable chemical warmer packs are available and can be used under the infant either in an incubator or on the radiant warmer.

A need for assisted ventilation presents additional problems. During hand bagging with an anesthesia bag, CPAP or PEEP is generally lost; in most situations, a simple oxygen tank is also used, limiting ventilation to 100% FIO_2. The anesthesia bag always should include a manometer because it is easy to reach pressures that can result in barotrauma complications, such as pneumothorax. A self-inflating resuscitator can be used for room air ventilation, but controlled oxygen delivery requires an additional tank and a blender. CPAP or PEEP can be maintained in an intubated infant using devices such as the NeoPuff. Particular care must be taken not to dislodge the endotracheal tube; small changes can result in either extubation or endobronchial intubation, particularly in a very premature infant. A laryngoscope, endotracheal tubes, and a facemask should be taken on transport in case the endotracheal tube is dislodged.

For all but the healthiest neonates, a physician experienced in neonatal resuscitation and who has the ability to

TABLE 32–3 Anesthetic Implications of Neonatal Syndromes

Syndrome	Clinical Manifestations	Anesthetic Implications
Adrenogenital syndrome	Defective cortisol synthesis Electrolyte abnormalities Virilization of girls	Supplement cortisol
Analbuminemia	Almost absent albumin	Sensitive to protein-bound drugs (thiopental, curare, bupivacaine)
Andersen syndrome	Midface hypoplasia Kyphoscoliosis	Difficult airway Impaired respiratory function
Apert syndrome	Craniosynostosis Hypertelorism Congenital heart disease possible	Difficult airway Increased ICP Cardiac evaluation, prophylactic antibiotics
Chiari malformation	Hydrocephalus Cranial nerve palsies Other CNS lesions	Aspiration precautions Vocal cord paralysis Latex allergy precautions
Arthrogryposis multiplex congenita	Contractures Restrictive pulmonary disease	Care in positioning Difficult airway Postoperative ventilation
Beckwith-Wiedemann syndrome	High birthweight Macroglossia Neonatal hypoglycemia	Difficult airway Monitor blood glucose, continuous glucose infusion, avoid boluses
CHARGE association	Coloboma Heart defects Atresia choanae Restricted growth and development Genital hypoplasia Ear deformities	Bilateral choanal atresia may require oral airway Cardiac evaluation, prophylactic antibiotics
Cherubism	Intraoral masses Mandibular, maxillary tumors	Difficult airway Possible cor pulmonale
Cornelia de Lange syndrome	Micrognathia, macroglossia Upper airway obstruction Microcephaly Congenital heart disease	Difficult airway Cardiac evaluation, prophylactic antibiotics
Cretinism	Macroglossia Goiter Decreased metabolic rate Myxedema Adrenal insufficiency	Difficult airway Delayed gastric emptying Fluid and electrolyte imbalance Sensitivity to cardiac and respiratory depressants Stress steroids
Cri du chat syndrome	Abnormal larynx, odd cry Microcephaly Hypertelorism, cleft palate Cardiac abnormalities	Difficult airway Cardiac evaluation, prophylactic antibiotics
Crouzon disease	Craniosynostosis Hypertelorism	Difficult airway Increased ICP
Dandy-Walker syndrome	Hydrocephalus Other CNS lesions	Increased ICP Latex allergy precautions
DiGeorge syndrome	Absent thymus, parathyroids Immunodeficiency Stridor Cardiac anomalies	Monitor calcium Exaggerated response to muscle relaxants Blood for transfusion irradiated Cardiac evaluation, prophylactic antibiotics

TABLE 32–3 Anesthetic Implications of Neonatal Syndromes—cont'd

Syndrome	Clinical Manifestations	Anesthetic Implications
Down syndrome (trisomy 21)	Atlantoaxial instability Macroglossia Congenital subglottic stenosis Duodenal atresia Cardiac defects (atrioventricular canal) Mental retardation	Difficult airway, use smaller tube Care with neck manipulation Cardiac evaluation, prophylactic antibiotics
Dwarfism	Odontoid hypoplasia, atlantoaxial instability Micrognathia, cleft palate	Care with neck manipulation Cardiac evaluation, prophylactic antibiotics
Eagle-Barrett syndrome (prune-belly syndrome)	Absent abdominal musculature Renal dysplasia Pulmonary hypoplasia	Respiratory insufficiency Renal failure
Ellis-van Creveld syndrome	Ectodermal defects, short extremities Congenital heart defects Chest abnormalities Abnormal maxilla	Difficult airway Impaired respiratory function Cardiac evaluation, prophylactic antibiotics
Goldenhar syndrome	Maxillary hypoplasia, micrognathia Cleft or high arched palate Eye and ear abnormalities Hemivertebra or vertebral fusion Congenital heart defects Spina bifida	Difficult airway Cervical spine evaluation Cardiac evaluation, prophylactic antibiotics
Holoprosencephaly	Midline deformities of face, brain Dextrocardia, ventricular septal defect Incomplete rotation of colon Hepatic malfunction, hypoglycemia Mental retardation, seizures	Difficult airway Postoperative apneas Cardiac evaluation, prophylactic antibiotics
Holt-Oram syndrome (heart-hand syndrome)	Radial dysplasia Congenital heart defects	Cardiac evaluation, prophylactic antibiotics
Jeune syndrome	Chest malformations Pulmonary hypoplasia and cysts Renal disease	Respiratory insufficiency, high risk of barotrauma Renal failure
Klippel-Feil syndrome	Fusion of cervical vertebrae Congenital heart defects	Difficult intubation Cardiac evaluation, prophylactic antibiotics
Möbius syndrome	Paralysis of cranial nerves VI and VII Micrognathia Recurrent aspiration Muscle weakness	Difficult airway Aspiration precautions
Mucopolysaccharidoses (Hurler and Hunter syndromes)	Macroglossia Hepatosplenomegaly Hydrocephalus Odontoid hypoplasia and atlantoaxial subluxation Valvular heart disease and cardiomyopathy	Difficult airway Abnormal coagulation Cervical spine instability Cardiac evaluation Increased ICP
Noonan syndrome	Micrognathia Webbed neck, short stature Congenital heart defects Hydronephrosis or hypoplastic kidneys	Difficult airway Cardiorespiratory evaluation Renal dysfunction
Oral-facial-digital syndrome	Cleft lip and palate Mandibular, maxillary hypoplasia Hydrocephalus Polycystic kidneys Digital abnormalities	Difficult airway Increased ICP Renal dysfunction

Zellweger syndrome	Craniofacial dysmorphism Glaucoma Peroxisomal abnormalities in kidney and liver	Difficult airway Impaired renal drug excretion Electrolyte imbalance Abnormal coagulation

CNS, central nervous system; ICP, intracranial pressure.

manage critically ill neonates should accompany the transport. In most situations, this person should be the anesthesiologist. Monitoring during transport varies depending on the condition of the infant. As a minimum, a pulse oximeter provides pulse rate and arterial oxygen saturation. In most ill neonates, electrocardiogram (EKG) and blood pressure should also be monitored, especially if the infant has an indwelling arterial line. Any pumps providing infusions to the infant should have adequate battery power to operate throughout the transport, especially if vasoactive drips are running. Syringe pumps provide a very stable rate and have a long battery life, and the entire system is compact, minimizing the equipment needing transport. These pumps also run accurately at a low (0.5 mL/h) rate so that concentrated infusions can be used, minimizing fluid delivered to the neonate.

A complete round of resuscitative medications also should accompany any infant being transported to or from the NICU. Some transports require multiple personnel. Transport of infants on extracorporeal membrane oxygenation or infants receiving inhaled nitric oxide is possible. With planning and adequate personnel, this task can be accomplished with minimal risk to the infant.

In some situations, if the surgical procedure is appropriate, if the surgeon is cooperative, and if a suitable locale is available, it may be preferable to perform some procedures in the NICU. Basic requirements for a suitable locale include a clean area that can be closed off from traffic and adequate equipment, including lights, surgical equipment and supplies, appropriate monitors, and anesthesia equipment. For premature neonates, an anesthesia machine is not usually needed, and a standard neonatal ventilator can be used. In many state-of-the-art NICUs, there is a dedicated operating room, with appropriate equipment, gases, and lights within the NICU, so that the most critically ill infants can be cared for with minimal transport.

Operating Room Equipment and Monitoring

The operating room should not merely replicate NICU capabilities; it should surpass them because the neonate is subjected to the additional stress and destabilization of surgery. It is helpful if the room itself has adequate temperature control because it may be necessary to increase room temperature to obtain a neutral thermal environment. Before draping, radiant heat lamps can be used, although care must be taken to not place the lamps too close to the infant because overheating can occur. The operating tables for neonates should use a heating pad. For longer cases, forced-air heaters such as the Bair Hugger can be used, with a "full access" disposable air blanket that is placed under the infant. Maintenance fluids, because they are given at a relatively slow rate, can usually be given at room temperature, but fluid warmers must be available for blood or faster fluid administration. Cooling is rarely necessary, but it is possible to overheat an infant if care is not taken. Temperature must be monitored. Core temperature is the best temperature to monitor. It can be measured with a rectal, nasopharyngeal, or esophageal probe. Bladder and tympanic membrane probes are rarely used in neonates because of size. Skin temperature is a poor second choice to core measurements.

Routine monitoring requirements for neonates are listed in Table 32-4. Continuous pulse oximetry has revolutionized anesthesia, and it is a standard of care in neonates as in adults. In some situations, particularly with congenital heart disease or PPHN, two pulse oximeters may be used to monitor preductal and postductal oxygen saturations. Heart rate is monitored from the pulse oximeter and the EKG. Disposable neonatal EKG pads are needed, from a size standard and because they may adhere better to the vernix caseosa-covered skin of the neonate. Noninvasive blood pressure can be measured, and most available machines have neonatal cuffs and a neonatal mode, which uses a smaller air volume for cuff inflation and is accurate in the neonate.

Urine output
Electrolytes

Invasive arterial blood pressure measurements from an indwelling line should be routine in most sicker or more premature infants. Common sites are the umbilical artery, either radial artery, and the femoral artery (as a last resort). Dorsalis pedis is rarely useful, but an axillary or posterior tibial line may be used occasionally. The arterial line site needs to be considered in relation to the clinical condition of the neonate; if coarctation of the aorta is present, a right radial line should be used. Similarly, if a right Blalock-Taussig shunt is planned, a left radial line is appropriate. Arterial lines in the neonate must be treated with the greatest delicacy. If blood is drawn from the line, a small syringe should be used, and suction should never be applied because the artery easily can go into spasm. The line always should be flushed gently, again with a syringe, and not with a pressure bag attached to the transducer. For smaller neonates, an intravenous infusion pump (not a pressure bag) should be used to keep a continuous flow through the transducer, to prevent inadvertent flushing and to limit the rate of fluid administration through the transducer (3 mL/h with the pressure bag versus 0.5 mL/h with the pump).

End-tidal CO_2 measurements also have become a standard of care, and they can be very helpful, but obtaining accurate measurements in a small neonate can be difficult. With a typical aspirating capnograph, the accuracy depends on the actual site of sampling, the type of anesthesia circuit used, and the volume of fresh gas flow through the circuit. Patient factors such as right-to-left shunt also may alter the values. The most accurate measurements are obtained using a low dead space circuit, with the sampling site in the endotracheal tube, not on the circuit. This location is accomplished by passing a small catheter into the endotracheal tube or via an endotracheal tube connector with a side port molded into it to which the capnograph sampling tubing can be attached. Blood glucose should be monitored intermittently during anesthesia; the importance of central venous pressure, urine output, and blood gases depends on the situation.

Previously, many anesthesia machines were equipped with a rudimentary, volume-limited, time-cycled ventilator, which even with a pediatric bellows was poorly suited for neonatal ventilation. Small tidal volumes were very difficult to set, and tidal volume and pressure varied tremendously depending on the fresh gas flow. In the best of hands, these ventilators are impossible to use with premature neonates. Several methods have been used to get around this limitation. The simplest is to use hand ventilation throughout the case, avoiding the ventilator. Although this method does allow some manual "feel" for pulmonary compliance, in many ways it limits the ability of the anesthesiologist to carry out other duties in caring for the patient. It also is very difficult to apply PEEP reproducibly when hand ventilating.

A second method is to bring an NICU ventilator to the operating room. Pressure-limited, time-cycled, and volume-limited ventilators are widely used to ventilate the smallest neonates. A disadvantage of pressure-limited ventilation is that tidal volume varies with changes in compliance, and care must be taken during surgery to monitor tidal volume and blood gases and end-tidal CO_2 to ensure adequacy of ventilation. Using a neonatal ventilator usually prevents the use of inhalational anesthetic agents, and it requires an intravenous anesthetic technique.

As a third choice, in some centers, ventilators have been retrofitted with vaporizers to allow for the use of inhalational agents. Newer anesthesia machines now available incorporate significantly more sophisticated ventilators, capable of either volume-limited or pressure-limited ventilation. These ventilators can be used in pressure-limited, time-cycled mode, and they incorporate a spirometer that can measure expired tidal volumes of 10 mL. Fresh gas flow is uncoupled from tidal volume, and changes in flows do not affect ventilation materially. PEEP can easily be added, without the external valves used in older machines. These machines can be used routinely in infants weighing 500 g.

The circle breathing system, with inspiratory and expiratory valves and incorporating a CO_2 absorber, has become standard in adult anesthesia. A major advantage is that a semiclosed technique with very low gas flows can be used, conserving anesthetic agent. Similar circle systems, appropriately sized for infants, with lower compliance tubing and smaller bags, are commonly used in neonates. Many centers continue to use variants of the Mapleson D circuit, which has no valves and does not use an absorber, depending on higher fresh gas flows to prevent rebreathing. This circuit has several advantages, particularly for smaller infants. The compliance of the tubing and the dead space are less; this can be crucial in the smallest infants with very small tidal volumes, allowing adequate ventilation with lower pressures. In the rare situation in which the infant is allowed to breathe spontaneously, the absence of valves markedly decreases the work of breathing. The Bain circuit is a variant of the Mapleson D circuit in which the fresh gas flow passes through a tube that is concentric with the expiratory tube; this makes a compact circuit and helps to minimize heat loss.

The operating room must be equipped with appropriately sized airway equipment, including Miller No. 0 and 1 blades, Macintosh No. 2 and 3 blades, uncuffed endotracheal tubes, and nasopharyngeal and oropharyngeal airways. An assortment of special blades should be available for difficult airway cases. The laryngeal mask airway (LMA) is a device that fits in the pharynx, covering the glottis and the esophageal opening. A cuff seals against the walls of the pharynx. LMAs do not occlude the esophagus and may notably increase the risk of aspiration during positive pressure ventilation. LMAs are available in small sizes, but are not commonly used in neonates. LMA can be very helpful in intubating some infants with congenital anomalies, such as Pierre Robin syndrome. Essentially, the LMA is positioned, and a fiberoptic bronchoscope is passed through the LMA and into the trachea. An endotracheal tube can be passed through the LMA over the bronchoscope. The neonatal fiberoptic bronchoscope is essential for difficult airway cases. This bronchoscope is limited by extreme flexibility, and it does not have a suction channel, but it passes through a 2.5-Fr tube.

General Anesthesia

Most infants who require surgery receive a general anesthetic. There is some interest in regional techniques, which may increase given questions concerning the safety of anesthetic agents, but at present this interest is limited. Successful delivery of general anesthesia in neonates requires knowledge of developmental pharmacology to predict and to understand the responses of premature infants to anesthetic drugs. Size has an effect on response to anesthetics, and developmental age has a profound impact on the dose response, distribution, and metabolism of these drugs.

INHALATIONAL AGENTS

Although common in older children, inhalational anesthesia has not been used extensively in premature infants. Use of inhalational agents was thought to be extremely dangerous, and based on reports of hemodynamic instability and cardiovascular collapse, it was believed that neonates would not tolerate these drugs. In reality, these agents can be used safely, although very careful administration is required. The anesthetic effect of inhalational agents depends on the partial pressure of the anesthetic in the brain and on the potency of the agent. For several reasons, very high partial pressures of the inhalational agents in the brain develop much more rapidly in neonates than in older children and adults. First, as already discussed, the ratio of alveolar ventilation (per minute) to FRC in neonates is 5:1 compared with 1.5:1 in adults, and consequently alveolar anesthetic concentration equilibrates with inspired concentration very quickly. Second, a greater fraction of the cardiac output in the neonate is distributed to the vessel-rich group and consequently the brain. Finally, the solubility of the inhaled anesthetics in blood is less in neonates than in adults.[35] Brain tissue equilibrates very quickly with the alveolar concentration of anesthetic and increases the risk of overdose in a neonate.

The potency of inhalational anesthetics is expressed using the minimum alveolar concentration (MAC). The MAC is the concentration at which 50% of patients exhibit no response to stimulation such as skin incision. MAC is related to postconceptional age and is lowest in very premature neonates, increasing to a peak at a postconceptional age of approximately 1 year, then decreasing progressively from childhood through adulthood. Figure 32-2 shows this relationship for isoflurane.[35] As shown, isoflurane is more potent (lower MAC) in premature neonates than in older infants, but this MAC is not markedly different from that of adults, and difficulties using inhalational anesthetics are related more to the rapid uptake and equilibration.

Common inhalational anesthetics are halothane, isoflurane, sevoflurane, and nitrous oxide. Desflurane and enflurane are rarely used in neonates. Inhalational anesthetics are complete anesthetics, with analgesic and amnesic properties. In previous years, halothane probably was the most commonly used because it is minimally irritating to the airway, and it can be used for a very smooth mask induction of anesthesia. Halothane is a significant myocardial depressant, however, and sensitizes the heart to catecholamine-induced arrhythmias. In

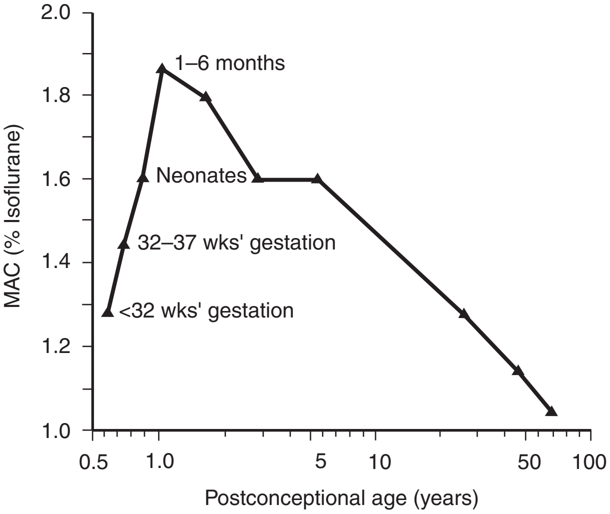

Figure 32–2. Minimum alveolar concentration (MAC) of isoflurane and postconceptional age on a semilogarithmic scale. *(From LeDez KM: The minimum alveolar concentration [MAC] of isoflurane in preterm neonates,* Anesthesiology *67:301, 1987.)*

contrast, isoflurane is very pungent and cannot be used for mask induction, but it has less effect on cardiac output than halothane. SVR is decreased by isoflurane, and hypotension can result, especially if preload is diminished. Moderate volume loading helps to minimize any decrease in blood pressure. Isoflurane also causes cerebral vasodilation, and in the absence of hypotension, cerebral bloodflow increases. In adults, isoflurane decreases cerebral metabolism and is cerebral protective.

Sevoflurane has become very popular in pediatric anesthesia for mask induction. It is not irritating to the airway, and it is almost insoluble in blood, so that equilibration between brain and alveolus occurs rapidly. Onset of anesthesia during mask induction is very fast. Cardiovascular effects are more similar to effects with isoflurane than with halothane. There is little published experience with sevoflurane in preterm infants, although it is used, primarily for mask inductions in healthier neonates. Sevoflurane has been associated with prolongation of the Q–T interval of the EKG in adults and infants; this may be of concern because a long Q–T interval has been associated with sudden death. There have been no reports, however, of intraoperative or postoperative complications related to sevoflurane and cardiac repolarization abnormalities, and it is uncertain if this is of any clinical concern.[38]

Nitrous oxide is an inhalational anesthetic, but it is not in the same class as the halogenated agents. It is a weak anesthetic, with a MAC of 104% in adults, so that to reach MAC, nitrous oxide would have to be provided at hyperbaric pressures. The need for oxygen as part of inspired gases prevents achievement of these levels. Nitrous oxide also is almost insoluble, and onset of effect is fast. Insolubility and the high concentration that is necessary for any meaningful effect cause nitrous oxide to enter progressively and to expand any gas-filled space in contact with the circulation, which rapidly leads to bowel distention or expansion of pneumothorax. If ventilation is interrupted for any reason, nitrous oxide also rapidly fills the alveoli, leading to dilution of the alveolar oxygen, producing a hypoxic mixture and rapid desaturation. For these reasons, nitrous oxide is best limited to adjunct use during mask induction, with a switch to an air-oxygen mixture during maintenance anesthesia. As previously discussed, all of the inhalational agents cause neuroapoptosis in animal studies.

INTRAVENOUS AGENTS

Intravenous agents include sodium thiopental, propofol, ketamine, various narcotics, and benzodiazepines. Other intravenous agents are rarely or never used in neonates. Sodium thiopental is an ultrashort-acting barbiturate used primarily as an induction agent. There is some evidence that premature neonates are more sensitive to thiopental than older infants, possibly because of decreased binding by serum proteins.[70] Thiopental is primarily a hypnotic, with little analgesic activity. Use is limited in smaller and sicker neonates because it has negative inotropic activity, and it is a peripheral vasodilator. Hypotension is common, particularly in volume-depleted patients.

Propofol is a phenol derivative supplied as an emulsion in lipid, which in older children and adults is used for induction and maintenance of anesthesia. Propofol has also been used for long-term sedation in adult and pediatric intensive care units, although there have been case reports of complications with long-term use in children, and the FDA has warned against such use before 16 years of age.[18,55] Recovery from the drug is rapid in adults because of redistribution and metabolism by liver and tissues. Propofol has less negative inotropic action compared with thiopental, but it is a powerful peripheral vasodilator, and hypotension is a common problem. The drug is designed as a complete anesthetic, but it does not have powerful analgesic effects, and for painful operations it should be used with narcotics. Propofol has been approved for children younger than 3 years, but there is little experience with the drug in premature infants.[18] A slower recovery with less fat and muscle to which to redistribute would be expected, and possibly slower hepatic metabolism owing to immaturity.

Ketamine, a phencyclidine derivative, provides good hypnosis and amnesia and excellent analgesia. It is used rarely in adults and older children because it can cause a dissociative state with confusion, hallucinations, and other severe psychological side effects. Ketamine stimulates the sympathetic nervous system and causes minimal respiratory and cardiovascular depression. Blood pressure may increase, and increased intracranial pressure is a concern in infants with hydrocephalus or infants at risk for intraventricular hemorrhage. Ketamine can be useful in breaking hypercyanotic spells in an infant with congenital heart disease and right-to-left shunt because it anesthetizes and increases SVR.

Benzodiazepines are agents that produce sedation, anxiolysis, and amnesia, but little analgesia. They are incomplete anesthetic agents, although in adults they have been very useful in combination with an opioid. Experience in neonates is very limited. Midazolam is a very short-acting benzodiazepine, and it has been the most commonly used in anesthesia. Metabolism is almost entirely hepatic, and it should be expected that duration would be prolonged by immature hepatic function in a preterm neonate. Midazolam vasodilates and can cause hypotension. In high doses, it can cause respiratory depression, although this is more common in conjunction with opioids. Midazolam and the longer acting benzodiazepine lorazepam have been used for sedation in the NICU with mixed results. The Cochrane Neonatal Collaborative Review Group performed a meta-analysis of several studies on sedation in the NICU using midazolam. In the two studies analyzed, infants treated with midazolam were more sedated (as judged by varying scoring systems) compared with infants treated with placebo. There were no differences in the incidence of intraventricular hemorrhage, pulmonary outcome, length of NICU stay, or mortality. The incidence of poor neurologic outcome was higher in the midazolam group, which at least raises questions as to the safety of midazolam infusion in these infants.[50]

Fentanyl, a synthetic opioid, is widely used in neonatal anesthesia, and it is the most commonly used anesthetic for premature infants. It has a wide safety margin and beneficial effects on hemodynamic stability. Fentanyl can block pulmonary hypertensive crises, and it is useful in infants with pulmonary hypertension, such as infants with congenital diaphragmatic hernia, PPHN, and some cardiac defects. Dosing has varied widely in the literature from 50 to 60 μg/min to 10 to 12.5 μg/min.[72] The pharmacokinetics of fentanyl in the early neonatal period is widely variable, depending on gestational and postnatal age and the type of surgery and medical problems of the infant.[56] Fentanyl is primarily metabolized in the liver, with only a small amount excreted unchanged by the kidneys. Clearance is lowest in the most premature infants, and it increases with gestational age and with age after birth, probably reflecting increasing hepatic maturation. Volume of distribution of fentanyl also seems to vary depending on gestational age and disease state. Neonates with increased intra-abdominal pressure seem to have slower clearance of fentanyl. Slower clearance is likely due to decreased hepatic bloodflow resulting from the increased intra-abdominal pressure. Such a relationship has been shown in neonatal lambs.[22,45]

Given the highly variable pharmacodynamics, fentanyl dosing needs to be individualized and titrated to effect. There is a fairly wide therapeutic range, and even with high doses, hemodynamic stability is maintained. All narcotics are respiratory depressants, however, and with higher doses of fentanyl, prolonged respiratory depression occurs, necessitating postoperative assisted ventilation.

Fentanyl in combination with a muscle relaxant has become the standard for anesthesia in premature neonates. Although fentanyl is a potent analgesic, it is not a complete anesthetic, and occasionally in adults, awareness has occurred with high-dose fentanyl alone. In the past, it was suggested that this was of minimal importance because neonates are not "aware," especially if pain was adequately treated. This belief is less well accepted today, and benzodiazepines or inhalational agents such as isoflurane are more commonly added to fentanyl anesthesia.

Other synthetic narcotics, such as alfentanil and sufentanil, rarely have been used in neonates. In adults, alfentanil is less potent than fentanyl, but it has a shorter half-life, whereas sufentanil is more potent than fentanyl. Pharmacokinetics in infants is probably similar to fentanyl, and there does not seem to be any significant advantage compared with fentanyl. Remifentanil is a new opioid whose duration of action is terminated by hydrolysis by tissue esterases. Consequently, remifentanil does not accumulate or have prolonged duration of action. A half-life of 4.4 minutes and a clearance of 80 mL/kg per minute have been reported in neonates,[14] but there is very little experience with this drug.

Morphine is the principal opium alkaloid, and it is the standard against which analgesics are measured. Morphine is less potent than fentanyl, but it has a longer duration of action and is more commonly used for postoperative pain. The duration of action of morphine is increased in premature infants. As with all narcotics, respiratory depression is a major side effect. In contrast to fentanyl, morphine causes histamine release, which limits its use as an anesthetic agent, although it is well accepted for analgesia and postoperative pain, and overall sedation.

Muscle relaxants are commonly used in anesthesia for neonates. They are often grouped according to mechanism of action (i.e., depolarizing versus nondepolarizing), but it is more important to consider rapidity of onset and duration of action. Succinylcholine chloride is the only depolarizing agent used at present, and it remains the standard for rapid onset and rapid disappearance. It is primarily used in one situation—for rapid-sequence intubation. In adults, it is also frequently used when a difficult airway is feared. Given the limited reserve and rapid desaturation in infants, the difficult airway problem is probably better handled with awake intubation, so that spontaneous ventilation can be maintained.

The ED_{95} (effective dose in 95% of the population receiving the dose) in neonates for succinylcholine is twice that of adults at 1.5 to 2 mg/kg. Action is terminated by metabolism by plasma pseudocholinesterase. Succinylcholine is not routinely used in children because of several rare but serious adverse reactions. In patients with myopathies or neurologic diseases, succinylcholine can cause overwhelming hyperkalemia, muscle necrosis, and cardiac arrest that is refractory to resuscitation. Bradycardia also occasionally occurs during intubation in infants with succinylcholine. For this reason, some anesthesiologists routinely administer atropine during a rapid-sequence intubation. Despite these reactions, succinylcholine at this point remains the choice for rapid-sequence intubation.

Nondepolarizing relaxants competitively inhibit acetylcholine at the neuromuscular junction. Pancuronium bromide is a long-acting relaxant, and it is probably the most commonly used relaxant in neonates when early extubation is not a problem. Onset occurs over several minutes, and it cannot be used for rapid sequence. Pancuronium has some vagolytic action and increases the heart rate. Vecuronium bromide is an intermediate-acting relaxant occasionally used in neonates. It has little effect on the cardiac system, although it may cause bradycardia in combination with narcotics. Cisatracurium besylate undergoes spontaneous degradation by a chemical process (Hofman elimination), and duration is not affected by liver or kidney function. Atracurium, its parent compound, is rarely used today because it causes histamine release. Rocuronium bromide is an agent with a rapid onset of action that can be used in place of succinylcholine for rapid sequence. Duration of action is dose dependent, and significantly longer than succinylcholine. Rapacuronium bromide also has a fast onset, but there is little information regarding use in neonates.

Most relaxants probably have a prolonged duration of action in premature neonates, and frequency of dosing should be determined using a nerve stimulator to measure response to four spaced stimuli (train-of-four response). At the completion of surgery, muscle relaxation with nondepolarizing agents should be reversed with an anticholinesterase, typically neostigmine, and an anticholinergic, usually atropine in neonates.

INDUCTION OF GENERAL ANESTHESIA

Most sick infants have intravenous access, and an intravenous induction can be performed. Premedication rarely is given to neonates, although some anesthesiologists recommend atropine before laryngoscopy and intubation. Healthier infants without intravenous access can undergo mask induction, typically with 50% nitrous oxide and sevoflurane, after which intravenous access is rapidly obtained.

Infants with a full stomach, most commonly infants with intra-abdominal disease, must have an intravenous rapid-sequence induction or an awake intubation. In rapid-sequence intubation, the infant is first preoxygenated with 100% F_{IO_2}, although this should perhaps be reconsidered. Thiopental and succinylcholine, with or without atropine, are rapidly pushed while an assistant performs the Sellick maneuver—pressure applied to the cricoid cartilage to prevent regurgitation of gastric contents. Positive pressure ventilation is not performed, and the infant is intubated expertly as soon as conditions are appropriate, usually after 45 to 90 seconds. There is little room for error with rapid sequence, and it should be performed only by individuals with significant expertise.

Awake intubation with continued spontaneous ventilation is an alternative, and it may be most appropriate for infants with difficult airways, such as in Pierre Robin and Goldenhar syndromes. Minimal sedation can be given, but protective airway reflexes should not be obtunded. When the airway is secured, induction can continue by intravenous or inhalational route. Management of the difficult airway requires careful planning and the availability of additional “trained hands.” A pediatric fiberoptic bronchoscope and a range of special-purpose laryngoscope blades may be useful. Pediatric ear, nose, and throat consultation may also be valuable. The laryngeal mask airway (LMA) may assist with ventilation, but it does not protect the airway. The pediatric bronchoscope also can be used to intubate through the LMA.

MAINTENANCE OF ANESTHESIA

Maintenance of anesthesia requires monitoring as previously discussed. Temperature must be carefully controlled, and adjustments in heating or cooling must be appropriately made. Fluid and metabolic requirements also must be carefully assessed throughout the course of the surgery. Fluids should be administered with an infusion pump to prevent inadvertent overload. It is usually easiest to calculate and administer maintenance fluids separately from replacement. Maintenance fluids should include glucose, unless the infant is known to be hyperglycemic. Intravenous hyperalimentation or a dextrose-electrolyte solution can be used, depending on the size, age, and clinical condition of the neonate. Third space losses should be initially replaced with a balanced crystalloid solution such as Ringer irrigation. Blood loss can also initially be replaced with crystalloid.

Third space losses can be impressive, ranging from 2 to 15 mL/kg per hour, especially during procedures with large amounts of bowel exposed, such as for repair of gastroschisis and omphalocele. Many infants, especially if they are hypoalbuminemic, should receive some replacement as colloid, usually 5% albumin. In the sickest neonates, transfusion with packed red blood cells, fresh frozen plasma, and platelets may be required. Urine output should be followed as one sign of adequate fluid replacement.

Ventilation should be carefully controlled. Use of oxygen has been discussed; if controlled ventilation is employed, care should be taken to avoid hyperventilation and subsequent hypocapnia. Using the ventilators on current anesthesia machines, it is easy to deliver excessive tidal volumes. Higher peak pressures can cause significant barotrauma. Hypocapnia causes marked decreases in cerebral bloodflow, which can easily be detected using cerebral oximetry employing near-infrared spectroscopy. This may be difficult to monitor because varying anesthesia circuits and adapters can result in widely varying dead space, and a variable offset between end-tidal CO_2 and the actual blood P_{CO_2}.

RECOVERY FROM ANESTHESIA

Emergence from anesthesia in the smallest and sickest premature infants is usually a prolonged event because these neonates are not typical candidates for extubation at the conclusion of surgery; instead, they require continued intensive care in the NICU. Immaturity of drug clearance systems also prolongs recovery from the effects of most anesthetic agents in these infants. Transport from the operating room involves the same considerations of temperature maintenance and airway management that have previously been discussed. Older and healthier infants usually can be extubated after surgery. Neuromuscular blockade should be reversed, as previously discussed. Hypothermia is a block to extubation if temperature control has not been adequate, and infants with hypothermia may need to be actively warmed.

The infant should have resumed regular rhythmic respiration; to achieve this, ventilation may need to be decreased toward the end of the anesthetic to allow P_{CO_2} to increase to mildly hypercapnic levels. Volume status must be adequate, and plasma hemoglobin should be close to normal. Flexion of the hip and contraction of the rectus abdominis muscle have been used as signs of adequate motor strength, and the infant usually begins to gag on the tube. Laryngospasm can occur on extubation, and the anesthesia personnel need to be ready to treat and reintubate if necessary.

As previously discussed, premature infants often experience periodic breathing, and there is a risk of postoperative apnea in these patients. Cote and coworkers[10] did a meta-analysis of data from eight separate studies and found wide variability among institutions. It was clear, however, that the risk of apnea was strongly inversely related to gestational age and postconceptional age. Anemia may be a risk factor for apnea, although this is controversial. In one study, the incidence of apnea was 80% in infants with hematocrits less than 30, and only 21% in infants with normal hematocrits.[69] Prolonged postoperative apnea (defined as apnea $>$15 seconds) occurs in approximately 70% of preterm infants less than 43 weeks' postconceptional age and decreases to less than 5% by postconceptional age 50 to 60 weeks.[43] Most episodes occur within 2 hours of anesthesia, but they may start as late as 12 hours and recur for as long as 48 hours. Caffeine has been used to reduce the risk of apnea, although it does not reduce this risk to zero.[68] A conservative approach is to avoid elective surgery and anesthesia until the former preterm infant reaches 60 weeks' postconceptional age, at which time the risk of postoperative apnea seems small. If surgery cannot be delayed, it is probably prudent to admit the infant after surgery and monitor the infant for 12 to 24 hours after surgery or after the last apneic episode.

Regional Anesthesia

Concerns about the neurotoxicity of general anesthetic agents have awakened new interest in regional anesthesia in children and neonates. Regional techniques have been rarely used in neonates, and most commonly have been combined with general anesthesia, with the primary indication control of postoperative pain. Widespread usage has been limited by the inherent technical difficulties in the smaller sized child and the relatively large size of available catheters and other materials.[30] Spinal and epidural (caudal) anesthesia is most common, although local infiltration or nerve block also is useful in certain specific procedures, such as circumcision, where a dorsal penile nerve block (DPNB) or penile ring block has been shown to be safe and effective.[36] Intercostal nerve blocks can be used for thoracotomy and flank incisions, whereas caudal anesthesia can be very effective for inguinal hernia surgery.

A regional technique without general anesthesia can be used in some neonates considered to be high risk, such as an infant with bronchopulmonary dysplasia. Spinal anesthesia without general anesthesia for inguinal hernia repair has been suggested as an alternative in infants at risk for postoperative apneas, although data are conflicting.[32] One major problem seems to be a high rate of failure of the technique, leading to the need for additional sedation. Although several studies show a decrease in the incidence of apnea with spinal anesthesia,[10,21] others see no difference,[34] but the infants receiving spinal anesthesia did have higher postoperative minimum oxygen saturations and heart rates. Supplemental sedation during the spinal anesthetic does increase the incidence of apneas.

Spinal anesthesia can be induced using a 25-gauge Quincke needle at the L4 or L5 level (below the cauda equina). Either tetracaine or lidocaine can be used depending on the length of procedure. Caudal anesthesia also is a useful option. The epidural space can be entered by the caudal route through the sacrococcygeal membrane. Caudal anesthesia can be given as a single injection, using a 22-gauge short-bevel needle, or a catheter can be threaded into the epidural space for continuous caudal anesthesia. With the continuous technique, the catheter can be threaded up into the epidural space, often high enough to give midthoracic anesthesia.[23] This technique seems to be well tolerated without significant hemodynamic effect. Caudal anesthesia requires a higher dosage of anesthetic, so that the possibility of an inadvertent intravascular injection is a concern.

In an infant at high risk, caudal or spinal anesthesia can be used without additional sedation for appropriate procedures, such as inguinal hernia repair. In this situation, simple nonpharmacologic comfort measures such as a pacifier are useful, and the technique seems to be well tolerated. More commonly, single-injection caudal anesthesia is used in combination with general anesthesia, which not only allows a "lighter" general anesthetic, but also is very effective for postoperative pain relief. After a caudal anesthesia with bupivacaine, most infants are free of pain immediately after inguinal hernia repair, with relief continuing for at least 3 to 4 hours. Spinal and caudal anesthesia are quite safe. The most significant but rare complication of spinal or caudal anesthesia is inadvertent intravascular injection of local anesthesia that results in seizures, arrhythmias, and cardiac arrest.

Local nerve blocks are rarely used in neonates. An exception is DPNB for neonatal circumcision. Safety and efficacy have been well documented, and in one prospective report of short-term complications, no significant problems were noted after DPNB in more than 7000 infants over an 8-year period.[60] Other simple methods, such as a sucrose-dipped pacifier, or a padded and physiologic restraint chair, further decrease objective signs of distress during circumcision performed with DPNB. Eutectic mixture of local anesthetic (EMLA) cream also has been used for neonatal circumcision. Although absorption of prilocaine, a component of EMLA, has the potential for causing methemoglobinemia, EMLA did not lead to measurable changes in methemoglobin levels in several studies and seems safe for premature and term infants.[64] Care should be taken, however. When used for circumcision, EMLA is more effective than no anesthesia, but it is not as effective as DPNB.[8,65] There are additional scattered reports of other uses for EMLA, including venous and arterial puncture, lumbar puncture, suprapubic puncture, and minor surgical procedures.[58]

More recent techniques, such as ultrasound, may make it easier and safer to perform other blocks in neonates. Transverse abdominis plain blocks and rectus sheath blocks may be performed in neonates with ultrasound guidance to obtain anterior abdominal wall anesthesia and periumbilical anesthesia. Transverse abdominis plain blocks in neonates have also been briefly reported,[25] although in both of these cases general anesthesia was also used, and the block was primarily for postoperative pain. Whether regional anesthesia can be used in neonates in the absence of general anesthesia is at present still unclear.

CHAPTER 33

Care of the Mother, Father, and Infant

Marshall H. Klaus, John H. Kennell, and William H. Edwards

The birth of a healthy normal newborn initiates a series of interactions with parents (particularly the mother) that is the orchestration of an intricate mix of genetics, epigenetics, evolutionary reflexes, and biology that promotes a beautiful and synergistic relationship designed to ensure survival. Many of the neural and hormonal pathways invoked are conserved through most mammalian species, with additional higher order responses unique to humans. New animal research techniques, such as the ability to study neural receptors, creation of *knockout* animals missing key components of pathways, and novel and innovative means of studying parenting in mammalian species, have led to greatly expanded understanding of the specific neural tracts, neurotransmitters, and hormonal actions involved. Further advances in genomics and proteonomics will continue to complement knowledge of highly conserved behaviors essential to survival. Human research has been necessarily restricted, but new techniques, such as functional magnetic resonance imaging (MRI), promise to bring new insights.

With each advance, the wonder of the intricacy of the synchrony between parent and newborn grows. Human development is sufficiently resilient to withstand substantial disruption of the normal postpartum sequence of events that initiate attachment. Significant problems of the infant (prematurity; congenital anomalies; transitional problems such as asphyxia, trauma, or peripartum infection) and problems of the mother (complications of pregnancy, depression) have more substantial capacity to disrupt normal processes. These complications carry a risk for adverse effects on long-term neurodevelopment. Even in the absence of identified medical complications such as intracranial hemorrhage and periventricular leukomalacia, extremely premature infants have a high incidence of learning problems, other mild forms of neural impairment, and a worrisome risk for severe handicaps.[61]

It is reasonable to assume that separation from parents and alteration in the normal processes of nurturing and parenting necessitated by medical problems requiring intensive care may play a role in abnormal development. Some preliminary studies indicate that the manner in which clinicians involve parents in care, care practices, and the environment where care is provided could be altered in ways that are better at promoting normal development. This chapter reviews the complex subject of supporting infants and their families during a particularly vulnerable time of human development. Klaus and Kennell, the original authors of this chapter, are pioneers in identifying the importance of this subject, and much of their work remains relevant and constitutes a core of this knowledge.

PROVISION FOR CARE

Events that are important to the formation of a mother's attachment to her infant include the following:

A. Before pregnancy
  1. Planning the pregnancy
B. During pregnancy
  1. Confirming the pregnancy
  2. Accepting the pregnancy
  3. Becoming aware of fetal movement
  4. Perceiving the fetus as a separate individual
  5. Labor
C. Birth and after
  1. Birth
  2. Touching and smelling the infant
  3. Seeing the infant
  4. Breast feeding the infant
  5. Caring for the infant
  6. Accepting the infant as a separate individual and welcoming the infant into the family

By observing and studying the mother and father in the context of these events, a description can be formed of how the parents of a normal, healthy infant build a bond with their infant.

BEFORE PREGNANCY

Psychological theory suggests that parenting behaviors are strongly programmed by the prospective parent's own childhood experience.[55] Children are socialized by the powerful process of imitation or modeling. Their behavior is influenced by how they are mothered or what they observe. Long before a woman becomes a mother, she has obtained a repertoire of mothering behaviors through observation, play, and practice. She already has learned whether infants should be picked up when they cry, when and how much they are carried, and whether they should be chubby or thin. It is an interesting phenomenon that these modes of conduct, absorbed when children are very young, become unquestioned imperatives for them throughout life. Unless adults consciously and painstakingly reexamine these learned behaviors, they are likely to repeat them unconsciously when they become parents.

PREGNANCY

Pregnancy seems to be a developmental crisis involving two particular adaptive tasks: the acceptance of pregnancy and the perception of the fetus as a separate individual.

Acceptance of Pregnancy

During the first stage of pregnancy, a woman must come to terms with the knowledge that she is going to be a mother. When she first realizes that she is pregnant, a woman often has mixed feelings. Many considerations, ranging from a change in her familiar patterns to more serious matters, such as economic and housing hardships or interpersonal difficulties, influence her acceptance of the pregnancy. This initial stage, as outlined by Bibring,[5] is the mother's identification of the growing fetus as an "integral part of herself."

Perception of the Fetus as a Separate Individual

The second stage of pregnancy involves a growing awareness of the infant in the uterus as a separate individual. It usually starts with the remarkably powerful event of quickening, the sensation of fetal movement. This perception occurs earlier for mothers who see their infant's movements on the screen during ultrasonography. During this period, the woman must begin to change her concept of the fetus from a being that is part of herself to a living infant who will soon be a separate individual. Bibring[5] believed that this realization prepares the woman for birth and physical separation from her child. This preparedness lays the foundation for a relationship with the child.

After quickening, a woman usually has fantasies about what the infant will be like, attributing some personality characteristics to the child and developing feelings of attachment.[5] At this time, she may further accept her pregnancy and show significant changes in attitude toward the fetus. Objectively, there usually is some outward evidence of the mother's preparation. She may purchase clothes or a crib, select a name, or rearrange her home to accommodate an infant—a human type of "nesting."

In contrast to the excitement and idealization of a normal child, most pregnant women also have hidden fears that the infant may be abnormal or may reveal some of their own secret inner weaknesses. Brazelton[6] clarified the importance of this turmoil for the subsequent development of attachment to the new infant:

> The prenatal interviews with normal primiparas, in a psychoanalytic interview setting, uncovered anxiety which often seemed to be of pathological proportions. The unconscious material was so loaded and distorted, so near the surface, that before delivery one felt an ominous direction for making a prediction about the woman's capacity to adjust to the role of mothering. And yet, when we saw her in action as a mother, this very anxiety and the distorted unconscious material could become a force for reorganization, for readjustment to her important new role. I began to feel that much of the prenatal anxiety and distortion of fantasy could be a healthy mechanism for bringing her out of the old homeostasis which she had achieved to a new level of adjustment. . . . I now see the shakeup in pregnancy as readying the circuits for new attachments, as preparation for the many choices which they must be ready to make in a very short critical period, as a method of freeing her circuits for a kind of sensitivity to the infant and his individual requirements which might not have been easily or otherwise available from her earlier adjustment. Thus, this very emotional turmoil of pregnancy and that in the neonatal period can be seen as a positive force for the mother's adjustment and for the possibility of providing a more individualized environment for the infant.

Life stresses, such as moving to a new geographic area, marital infidelity, death of a close friend or relative, previous abortions, or loss of previous children, that leave the mother feeling unloved or unsupported or that precipitate concern for the health and survival of either her infant or herself may delay preparation for the infant and retard bond formation.[10] After the first trimester, behaviors that are a reaction to stress and suggest rejection of pregnancy include a preoccupation with physical appearance or negative self-perception, excessive emotional withdrawal or mood swings, excessive physical complaints, absence of any response to quickening, or lack of any preparatory behavior during the last trimester. Caregivers' ability to help parents during times of emotional turmoil probably has a strong influence on determining whether the pregnancy will be a positive or negative experience in the woman's life.[7]

A mother's and father's behavior toward the infant after birth is derived from a complex combination of their own genetic endowments, the infant's responses to the parents, a long history of interpersonal relationships with their own families and with each other, experiences with this or previous pregnancies, the practices and values of their cultures, their socioeconomic status, and, probably most importantly, the way they were raised by their own parents. The mothering or fathering behavior of each woman and man, the ability of each parent to tolerate stresses, and the needs each parent has for special attention differ greatly and depend on a mixture of these factors.

It is unclear how fixed and unchangeable these determinants are or the degree to which they may be influenced during the crisis of birth by the environment and care practices. The attitudes, statements, and practices of the nurses and physicians in the hospital; whether there is early suckling and rooming-in or separation from the infant in the first days of life; the infant's temperament; and whether the infant is healthy, sick, or malformed all may affect the relationship. Most mothers and fathers develop warm and close attachments with their infants. Mothering disorders, ranging from mild anxiety (e.g., persistent concerns about an infant after a minor problem that has been completely resolved in the nursery) to the most severe manifestation, the battered child syndrome, occur with a few parents. It is crucial to develop hospital care practices that minimize the risk of contributing to parenting problems, such as by avoiding unnecessary separation of an infant from parents.

Figure 33-1 is a schematic diagram of the major influences on parental behavior and the resulting disturbances that may arise from them. Experiences during labor, parent-infant separation, and hospital practices during the first hours and days of life are the most easily manipulated variables in this scheme. More recent studies have partly clarified some of the steps in mother-infant attachment during this early period.

To minimize the number of unknowns for a mother while she is in the hospital, she and the father (or other supportive companion who stays with her throughout labor and delivery) should visit the maternity unit to see where labor and delivery will take place. They should learn about delivery routines and all procedures and medication the mother will receive before, during, and after delivery. Reducing the possibility of surprise increases confidence during labor and delivery. For an adult, just as for a child entering the hospital for surgery, the more meticulously detailed every step and event is in advance, the less will be the subsequent anxiety. The less anxiety the mother experiences while delivering and becoming attached to her infant, the better will be her immediate relationship with the infant.

LABOR

Before childbirth moved from the home to the hospital, the practice in industrialized nations was for women in the community to support the mother in labor, often with the assistance of a trained or untrained midwife. In all but 1 of the 128 cultures studied by anthropologists, a family member or friend, usually a woman, remained with the mother during labor and delivery. Although more fathers, relatives, and friends have been allowed into labor and delivery rooms in the past 25 years, many mothers still labor and deliver in some hospitals without continuous emotional and physical support.

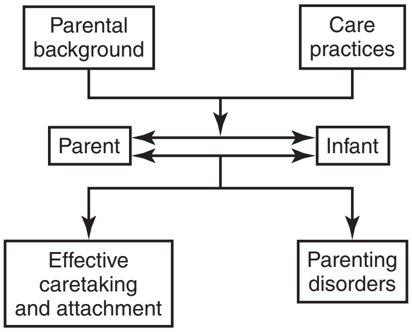

Figure 33–1. Major influences on parent-infant attachment and outcomes.

The clinical value of continuous emotional and physical care during childbirth by a trained woman called a *doula* is supported by the results of the 16 randomized clinical trials conducted over more than two decades.[24] Beneficial findings are consistent across the studies despite different cultural, medical, and social practices.

A meta-analysis by Scott and colleagues[52] revealed that continuous social support during labor and delivery has a significantly more beneficial impact on childbirth outcomes than intermittent support. In six studies, the intermittent presence of a doula with mothers compared with the absence of any doula support was not significantly associated with any improved outcomes. In contrast, in five studies, continuous support for mothers was significantly associated with a 36% reduction in the need for analgesia, a 71% decrease in the need for oxytocin augmentation, a 57% reduction in the use of forceps, a 51% decrease in cesarean sections, and an average shortening of the duration of labor by 98 minutes. Some of the original studies may have underestimated the positive effects of social support during childbirth by not requiring support to be provided continuously to experimental subjects.

The results of the study by Wolman and coworkers[69] in South Africa revealed the favorable effects of continuous support during labor on the subsequent psychological health of the women and infants in the group of women with support from a doula. At 24 hours, the mothers with a doula had significantly less anxiety than the mothers without doulas, and fewer doula-supported mothers considered the labor and delivery to have been difficult. At 6 weeks postpartum, there was a significantly greater proportion of women breastfeeding in the doula group (51% versus 29%), and feeding problems were significantly fewer in the doula group (16% versus 63%). The doula-supported mothers noted that it took an average of 2.9 days for them to develop a relationship with their infant compared with 9.8 days for the mothers without doulas. These results suggest that support during labor expedited the doula-supported mothers' readiness to bond with their infants. Using other measures, mothers in the doula group were again significantly less anxious, had scores on the depression scale that were significantly lower than those of the control group, and had higher levels of self-esteem at 6 weeks postpartum. They also felt significantly more satisfied with their partner 6 weeks after the birth (71% versus 30%) and felt their infant was better than an average infant—more beautiful, more clever, and easier to manage—whereas the control mothers perceived that their infant was slightly less attractive than a standard infant.

In a 1998 study, 413 nulliparous women in early labor were randomly assigned to receive epidural analgesia, narcotic medication, or continuous support by a doula.[37] All the infants and mothers had uneventful hospital courses. Thirty-five mothers and their infants were randomly chosen from each of the three groups for further study. There was no contact with the families until a visit to the home was made by trained and blinded observers 2 months after delivery for a 2-hour period. The interactions between mother and infant were scored on a scale of 1 to 7, with graded definitions of the mother's physical contact, visual attention, and affectionate behaviors toward her child. The mother-infant interaction was assessed five times during the visit—for example, during a feeding and while the mother changed the infant. Interrater reliability was high. The mother-infant interaction scores showed significant differences between the doula-supported mothers and the group of mothers who had epidural and narcotic medication. Overall, the average mother-infant interaction scores at all five observation points for the doula and for the two nondoula groups were significantly different ($P < .001$). These scores suggest that providing a laboring woman with the continuous support of a doula results in a significantly more positive level of interaction with her infant 2 months after delivery.

Hodnett and colleagues[24] concluded that, "Continuous support during labour should be the norm, rather than the exception. All women should be allowed and encouraged to have support people with them continuously during labour. In general, continuous support from a caregiver during labour appears to confer the greatest benefits when the provider is not an employee of the institution, when epidural analgesia is not routinely used, and when support begins in early labour."

A renewed interest in the first minutes, hours, and days of life has been stimulated by several provocative behavioral and physiologic observations in mothers and infants. These assessments and measurements have been made during labor, birth, and the immediate postnatal period, and at the beginning breast feedings. They provide a compelling rationale for major changes in care in the perinatal period for mothers and infants. These findings fit together to form a new way to view the mother-infant dyad.

FIRST HOURS AFTER BIRTH

Nearly 90% of newborns require no special intervention at birth. Suctioning is not typically required with clear amniotic fluid, and clearing of the upper airway can be accomplished by simply wiping the infant's mouth and nose (see also Chapter 27). Vigorous infants with meconium-stained amniotic fluid may need suctioning of the mouth and nose with only a soft bulb syringe.[29] Separating the newborn from the mother to administer the initial steps in stabilization is also not needed. The newborn should be thoroughly dried except for the hands with warm towels after birth to avoid the loss of heat, and once it is clear that the infant has good color and is active and normal (usually within 1 to 3 minutes), he or she can be given to the mother. At this time, the warm and dry infant can be placed between the mother's breasts, on her abdomen, or, if she desires, next to her. The transition from life in the womb to existence outside the uterus is made much easier when the newborn is kept close to the mother's body. The newborn recognizes the mother's voice and smell,[60] and her body provides thermoregulation.[9] In this way, the infant can experience sensations similar to those of the last several weeks of uterine life (Fig. 33-2).

The mother has an intense interest in her newborn baby's open eyes. When left alone with her infant in the first hour of life, 85% of what a mother says is related to the infant's eyes: "Please look at me" and "If you look at me, I know you love me."[33] In the first 45 minutes of life, the infant is awake and alert and in the quiet alert state.

Figure 33–2. A mother and her infant shortly after birth. *(From Klaus MH et al:* Amazing newborn, *Cambridge, MA, 1985, Perseus, p 137, with permission. Copyright Suzanne Arms Wimberley.)*

One of the most exciting observations is the discovery that the newborn has the ability to find the mother's breast and to decide when to take the first feeding.[47] When placed on the mother's abdomen after brief drying of the body and assessment, the infant usually begins with a time of rest and quiet alertness, rarely crying and often appearing to take pleasure in looking at the mother's face. Around 30 to 40 minutes after birth (sometimes longer), the newborn begins making mouthing movements, sometimes with lip smacking, and shortly after, saliva begins to pour down the infant's chin. When placed on the mother's abdomen, infants maneuver in their own ways to reach the nipple. They often use small pushups, lowering one arm first in the direction they wish to go. These efforts are interspersed with short rest periods. Sometimes infants change direction midcourse. These actions take effort and time, but are rewarding for the parents and the infant.

Figure 33-3 shows a newborn successfully navigating. At 10 minutes of age, the newborn first begins to move toward the left breast. Repeated mouthing and sucking of the hands and fingers is commonly observed (see Fig. 33-3A). With a series of pushups and rest periods, the infant gets to the right breast completely unassisted (see Fig. 33-3B). The infant, with lips on the areola, now begins to suckle effectively while closely observing the mother's face (see Fig. 33-3C).

This sequence may be helpful to the mother and the infant because the massaging and suckling of the breast induces an oxytocin surge into the mother's bloodstream, which may help contract the uterus, expelling the placenta and closing off many blood vessels in the uterus, reducing bleeding. In addition, the stimulation and suckling help in the manufacture of not only prolactin in the mother, but also oxytocin in the brain of the mother and the infant. It is likely that oxytocin plays a role in bonding in humans in ways similar to mammals where it is associated with initiating maternal behavior (see later).[25] The mother and infant apparently are well adapted for these first moments together.

The odor of the nipple seems to guide a newborn to the breast.[60] If the right breast is washed with soap and water, the infant crawls to the left breast, and vice versa. If both breasts

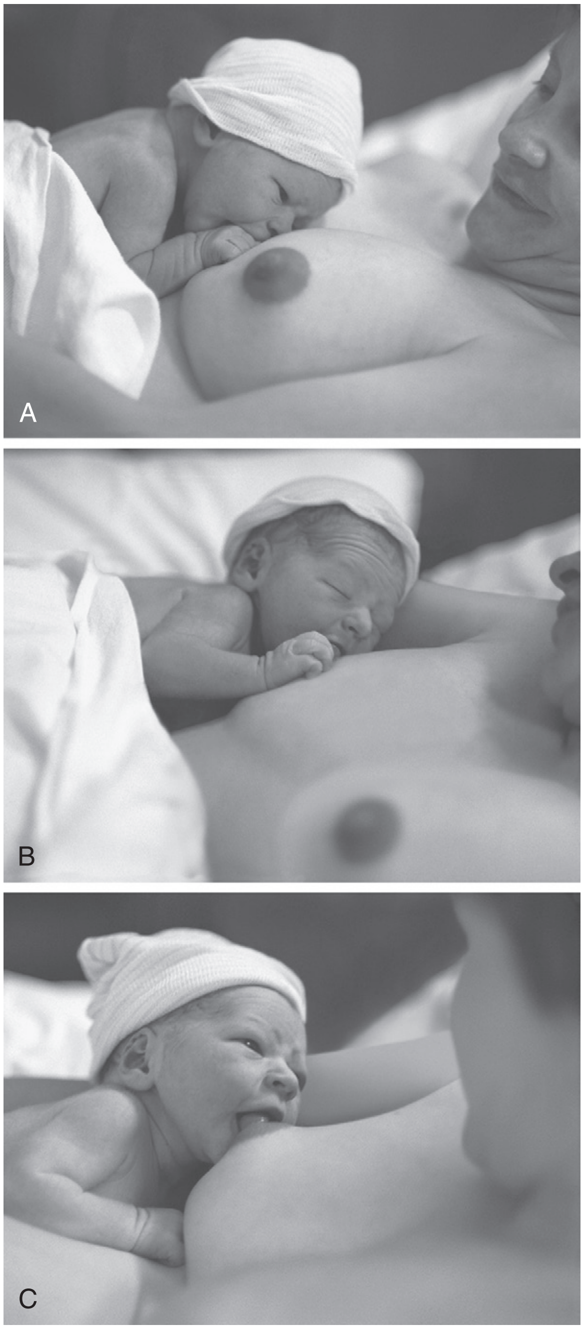

Figure 33–3. **A**, Infant about 15 minutes after birth, sucking on the unwashed hand and possibly looking at mother's left nipple. **B**, An arm pushup, which helps the infant to move to mother's right side. **C**, At 45 minutes of age, the infant moved to the right breast without assistance and began sucking on the areola of the breast. The infant has been looking at the mother's face for 5 to 8 minutes. *(Photographed by Elaine Siegel. From Klaus MH, Klaus PH:* Your amazing newborn, *Cambridge, MA, 1998, Perseus, pp 13, 16, and 17.)*

are washed, the infant goes to the breast that has been rubbed with the amniotic fluid of the mother. The special attraction of the newborn to the odor of the mother's amniotic fluid may reflect the time when the fetus swallowed the liquid in utero. Amniotic fluid seems to contain a substance that is similar to some secretion of the breast, although not the milk. Amniotic fluid on the infant's hands probably also explains part of the interest in sucking the hands and fingers seen in the photographs in Figure 33-3. This early hand-sucking behavior is markedly reduced when the infant is bathed before the initial crawl. Washing the infant's hands and the mother's breasts should be delayed so that the taste and smell of the mother's amniotic fluid is not removed.

Many abilities enable an infant to do these tasks. Stepping reflexes help the newborn push against the mother's abdomen to propel him or her toward the breast. The ability to move a hand in a reaching motion enables the infant to claim the nipple. Taste, smell, and vision all help the newborn find the breast.[35] Muscular strength in the neck, shoulders, and arms helps newborns bob their heads and do small pushups to inch forward and from side to side. Human infants, similar to other infant mammals, apparently know how to find their mother's breast.

Swedish researchers have shown that a normal infant who is dried and placed naked on the mother's chest and then covered with a blanket maintains body temperature as well as an infant who is warmed with an elaborate, high-tech heating device, which usually separates the mother and infant.[9] The same researchers found that when the infants have skin-to-skin contact with their mothers for 90 minutes after birth, they cry hardly at all compared with infants who were dried, wrapped in a towel, and placed in a bassinet. In one study of mothers who received no pain medication, their infants were placed on their abdomen, and vitamin K injection and application of eye ointment were delayed for 1 hour. Of 16 infants, 15 were observed to make the trip on their own to their mother's breast, latch on, and begin to suckle effectively.[47] It seems likely that each of these features—the crawling ability of the infant, the decreased crying when close to the mother, and the warming capacity of the mother's chest—are adaptive and evolved genetically to help preserve the infant's life.

Based on these findings, the American Academy of Pediatrics recommends in a policy statement on breast feeding that "Healthy infants should be placed and remain in direct skin-to-skin contact with their mothers immediately after delivery until the first feeding is accomplished."[2] It is recommended further that vigorous suctioning be avoided, and that weighing, measuring, bathing, needle sticks, and eye prophylaxis be delayed until after the first feeding is completed.

The United Nations International Children's Fund (UNICEF) has also incorporated these evidence-based practices in its Baby-Friendly Hospital Initiative (BFHI). Among the 10 steps for a hospital to achieve Baby-Friendly designation are to "Help mother initiate breastfeeding within one hour of birth," and "Practice 'rooming in'—allow mothers and infants to remain together 24 hours a day."[59]

After the introduction of BFHI in maternity units in several countries throughout the world, an unexpected observation was made. In Thailand, in a hospital in which numerous infants were abandoned by their mothers, the use of rooming-in and early contact with suckling in the first hour significantly reduced the frequency of abandonment (from 33 of 10,000 births to 1 of 10,000 births a year).[8] Similar observations were made in Russia, the Philippines, and Costa Rica when early contact and rooming-in were introduced. Kramer[36] conducted a cluster-randomized trial of implementing BFHI in 16 hospitals in Belarus compared with 15 control hospitals. In this study of 16,442 mother-infant pairs, the author found that infants from the study hospitals were more likely to be exclusively breastfed at 3 months (43.3% versus 6.4%; $P = .001$) and 6 months (7.9% versus 0.6%; $P = .01$) and receiving any breast milk feedings at 12 months. These reports are additional evidence that the first hours and days of life are a sensitive period for human mothers.[33]

Physiologic explanations for the natural events surrounding birth that lead to successful attachment and to the initiation of breast feeding have been sought in many animal and human studies. The role of oxytocin seems to be particularly important.[18,25] Hypothalamic oxytocin gene expression and receptor binding increased in postpartum female voles,[63] and oxytocin knockout mice exhibit deficits in maternal behavior, including lower pup retrieval and less licking and self-grooming.[46] Dilation of the cervical os in sheep releases oxytocin within the brain, which seems to be important for the initiation of maternal behavior and facilitation of bonding between mother and infant.[32]

Measurements of plasma oxytocin levels in 18 healthy women who had their infants on their chests with skin-to-skin contact immediately after birth showed significant elevations compared with the antepartum levels, and a return to antepartum levels at 60 minutes. For most women, a significant and spontaneous peak concentration was recorded about 15 minutes after delivery, with expulsion of the placenta.[42] Most mothers had several peaks of oxytocin up to 1 hour after delivery. In humans, there is a blood-brain barrier for oxytocin, and only small amounts reach the brain via the bloodstream. Multiple oxytocin receptors in the brain are supplied, however, by production in the brain. Increased levels of brain oxytocin result in slight sleepiness, calmness, an increased pain threshold, and feelings of increased love for the infant. During breast feeding, elevated blood levels of oxytocin seem to be associated with increased brain levels; women who exhibit the largest plasma oxytocin concentrations are the sleepiest. Not only may the vigorous oxytocin release after delivery and with breast feeding help contract the uterine muscle to prevent bleeding, but it also may enhance bonding of the mother to her infant.

Further evidence that oxytocin may be important in human maternal affiliation comes from Feldman and associates.[18] In a study of 62 women, oxytocin levels were measured in early pregnancy, late pregnancy, and postpartum. The investigators found that oxytocin levels in early pregnancy and the postpartum period were significantly correlated with a clearly defined set of maternal bonding behaviors, including gaze, vocalizations, positive effect, and affectionate touch; attachment-related thoughts; and frequent checking of the infant.

We hypothesize that a cascade of interactions between the mother and the infant occurs during this early period, locking them together and ensuring further development of attachment. The remarkable change in maternal behavior with just the touch of the infant's lips on the mother's nipple; the effects of additional time for mother-infant contact; the reduction in abandonment with early contact, suckling, and rooming-in; and the increased maternal oxytocin levels shortly after birth in conjunction with known sensory, physiologic, immunologic, and behavioral mechanisms all contribute to the attachment of the mother to the infant. These assessments and measurements have been made during labor, birth, and the immediate postnatal period, and at the beginning breast feedings. They provide a compelling rationale for how care should be provided in the perinatal period for the mother and the infant. These findings fit together to form a rationale for recognizing the importance of optimal support of the mother-infant dyad in this critical early period.

FIRST DAYS OF LIFE

Immediately after birth, parents enter a unique period in which their attachment to their infant usually begins to blossom and in which events may have many effects on the family. The first feelings of love for the infant are not instantaneous with the initial contact. Many mothers express distress and disappointment when they do not experience feelings of love for their infant in the first minutes or hours after birth. Findings from two studies of normal, healthy mothers in England show this to be common. MacFarlane and associates[38] asked 97 mothers from Oxford, "When did you first feel love for your baby?" The replies were as follows: during pregnancy, 41%; at birth, 24%; first week, 27%; and after the first weeks, 8%. In another study of two groups of primiparous mothers, 40% recalled that their predominant emotional reaction when holding their infants for the first time was indifference.[48] The same response was reported by 25% of 40 multiparous mothers. Another 40% of each group felt immediate affection. Most mothers in both groups had developed affection for their infants within the first week. The onset of this maternal affection after childbirth was more likely to be delayed if the membranes were ruptured artificially, if the labor was extremely painful, or if the mothers had been given meperidine.

Information in closely related fields has greatly augmented our understanding of the beginning of parent-infant interactions. Detailed studies of the amazing behavioral capacities of a normal neonate in the quiet alert state have shown that the infant sees, hears, imitates facial gestures, and moves in rhythm to the mother's voice in the first minutes and hour of life, resulting in a beautiful linking of the reactions of the two and a synchronized "dance" between the mother and infant.[35] The infant's appearance, coupled with this broad array of sensory and motor abilities, evokes responses from the mother and father and provides several channels of communication that are most helpful in the initiation of a series of reciprocal interactions and in the process of attachment.

With the mother's strong desire to touch and see her child, nature has provided for the immediate and essential union of the two. The alert newborn rewards the mother for her efforts by following her with his or her eyes, maintaining their interaction and kindling the tired mother's fascination with her infant.

SENSITIVE PERIOD

The period of labor, birth, and the following several days can probably best be defined as a sensitive period. During this perinatal period, the mother and probably the father are strongly influenced by the quality of care they themselves receive. The more appropriately and humanely the mother is cared for, the more sensitive she is 6 weeks later in the care of her own infant.

Winnicott[67] reported a special mental state of the mother in the perinatal period that involves a greatly increased sensitivity to, and focus on, the needs of the infant. He indicated that this state of "primary maternal preoccupation" starts near the end of pregnancy and continues for a few weeks after the birth of the infant. A mother needs nurturing support and a protected environment to develop and maintain this state. This special preoccupation and the openness of the mother to her infant are probably related to the bonding process. Winnicott[67] wrote that "only if a mother is sensitized in the way I am describing, can she feel herself into her infant's place, and so meet the infant's needs." In the state of primary maternal preoccupation, the mother is better able to sense and provide what her new infant has signaled, which is her primary task. If she senses the needs and responds to them in a sensitive and timely manner, mother and infant establish a pattern of synchronized and mutually rewarding interactions.[33] This parent-infant synchrony continues and contributes to creating a secure attachment.[19]

Winnicott[68] also postulated that imitative behaviors by parents taking the infants' cues are important to help the infant develop a concept of self. He noted that some infants have mothers who do not imitate the infant, and the infants do not see themselves. He postulated that in these situations, the infant's own creative capacity may atrophy, and they may look for other ways to get to know themselves from the environment. Winnicott's important observation was that in normal mother-infant dyads, the mother often followed or imitated the infant.

Trevarthen,[58] using fast-film technique, confirmed these observations in mothers and infants, and noted that mothers imitate their infants during spontaneous play. He also noted that the mother's imitation of the infant's behavior, rather than the reverse, sustained their interaction and communication. Detailed analysis revealed that mothers were studiously imitating the infant's expression with a lag of a few tenths of a second; the infant was choosing the rhythm.

In a series of creative experimental manipulations of infant-mother face-to-face interactions, Field[20] noted that mothers and normal full-term infants were interacting about 70% of the time in their spontaneous play. When the mother was asked to increase her attention-getting behavior (stimulation), her activity increased to 80% of the time, however, and the infant's gaze decreased to 50%. When the mother imitated the movements of the infant, which greatly reduced her activity, the infant's gaze time greatly increased. When the infants were preterm infants considered to be high risk, Field[20] noted that in the spontaneous situation, the mothers were interacting 90% of the time, but the infant was looking only 30% of the time. If the mother was told to use attention-getting gestures, her activity increased to more than 90% of the time, and the infant's gaze decreased further. If her interactions were decreased by asking her to imitate the infant's movements, the infant's gaze increased greatly. Although generally the mother's activity was aimed at encouraging more activity or responsiveness from the premature infant, the approach seemed to be counterproductive, leading to less, rather than more, infant responsiveness.

In an innovative and well-designed series of studies, Kaitz and colleagues[27,28] investigated whether normal mothers were able to discriminate their own infants from other infants on the basis of smell, touch, face recognition, or cry recognition after several hours with their infants. They tested each sense separately and found that smell was the most salient. After 5 hours of contact, nearly 100% of mothers were able to recognize the smell of their own infant. Parturient women know their infant's distinctive features after minimal exposure using olfactory and tactile cues, whereas discrimination based on sight and sound takes longer to develop. Kaitz and colleagues[27,28] suggested that this order may reflect a fundamental property humans share with other species.

The clinical observations of Rose and associates[50] and Kennell and coworkers[31] suggested that affectional ties can be easily disturbed and may be permanently altered during the immediate postpartum period. Relatively mild conditions in the newborn (e.g., slight elevations of bilirubin levels, slow feeding, need for additional oxygen for 1 to 2 hours, and the need for incubator care in the first 24 hours for mild respiratory distress) seem to affect the relationship between mother and infant. The mother's behavior is often disturbed during the first year or more of the infant's life, even though the infant's problems are completely resolved before discharge and often within a few hours. That early events have long-lasting effects is a principle of the attachment process. A mother's anxieties about her infant in the first few days after birth, even about a problem that is easily resolved, may affect her relationship with the child long afterward. This has been described by Green and Solnit[22] as the "vulnerable child syndrome."

In the past 30 years, multiple studies have focused on whether additional time for close contact in the first minutes, hours, and days of life may alter parents' later behavior with their infant. In many biologic disciplines, these moments have been called *sensitive periods*. In most examples of a sensitive period in biology, the observations are made of the young of the species, however, rather than of the adult. Studies by Brazelton and colleagues[7] and others have shown that if nurses spend as few as 10 minutes helping mothers discover some of their newborn infant's abilities, such as turning to the mother's voice and following the mother's face or imitation, and assisting mothers with suggestions about ways to quiet their infants, the mothers became more appropriately interactive with their infants face to face and during feedings at 3 and 4 months of age.

O'Connor and colleagues[43] performed a randomized trial with 277 mothers in a hospital that had a high incidence of parenting disorders. One group of mothers had their infants with them for an additional 6 hours on the first and second day, but they had no early contact. The routine-care group began to see their infants at the same age, but only for 20-minute feedings every 4 hours, which was the custom throughout the United States at that time. In the follow-up studies, 10 children in the routine-care group experienced parenting disorders, including child abuse, failure to thrive, abandonment, and neglect during the first 17 months of life; this compared with only 2 cases in the experimental group who had 12 additional hours of mother-infant contact. A similar study in North Carolina that followed 202 mothers during their infant's first year of life did not find a statistically significant difference in the frequency of parenting disorders.[53]

Evidence suggests that many of these early interactions also occur between the father and newborn. Parke,[45] in particular, showed that when fathers are given the opportunity to be alone with their newborns, they spend almost exactly the same amount of time as mothers do, holding, touching, and looking at them. In the triadic situation, the father tends to hold the infant nearly twice as much as the mother, vocalizes more, and touches the infant slightly more, but he smiles at the infant significantly less than the mother. The father plays the more active role when both parents are present, in contrast to the cultural stereotype of the father as a passive participant. In this triadic interaction, the mother's overall interaction declines. All but one of the fathers whom Parke studied had attended labor and birth, and this could be expected to produce an unusual degree of attachment. Parke[45] believed that fathers must have an extensive early exposure to infants in the hospital and home, where the parent-infant bond is initially formed. He indicated that fathers are much more interested in and responsive toward their infants than U.S. culture has previously acknowledged.

In a significant observation of fathers, Rödholm[49] noted that paternal caregiving greatly increased when the father was allowed to interact and establish eye-to-eye contact with his infant for 1 hour during the first hours of life. Keller and associates[30] reported that, compared with a traditional contact group, a group of fathers who received extended postpartum hospital contact with their infants engaged in more en face behavior and vocalization with their infants and were more involved in infant caretaking responsibilities 6 weeks after the infant's birth. They also had higher self-esteem scores than fathers in the control group.

Debate continues on the interpretation and significance of studies of the effects that early and extended contact for mothers and fathers with their infants have on their ability to bond.[34] All sides agree, however, that all parents should be offered early and extended time with their infants.[33] An extensive review of this subject can be summarized as follows: The restriction of early postnatal mother-infant interaction (which used to be a common feature of the care of women giving birth in hospitals, and still remains in some settings) has undesirable effects.[14] Disruption of mother-infant interaction in the immediate postnatal period may set some women on the road to breast-feeding failure and altered subsequent behavior toward their children. Pediatricians, psychologists, and others have debated this issue, but skepticism does not constitute grounds for preserving hospital routines that lead to unwanted separation of mothers from their infants. Hospital routines should minimize unnecessary separation of newborns from their parents.

PREMATURE OR SICK INFANTS

Given the importance of the close contact and interaction described in establishing parent-child relationships under normal circumstances, it is not surprising that parents of premature or sick infants requiring care in the neonatal intensive care unit (NICU) experience anxiety and stress. Singer and associates[54] showed that almost half of mothers of infants with very low birth weight at 1 month of age had signs of overall distress, with 13% having severe signs, and 9% having signs of severe depression. Of mothers of term infants at the same age, 17% showed mild signs of distress, and only 1% showed severe signs. By 2 years of age, the mothers of infants with very low birth weight without complications had similar measures of distress as term mothers, whereas mothers of infants who had chronic lung problems continued to show psychological distress.

Parents who live a distance from perinatal care centers may experience additional separation because of the necessity of transporting their child to a regional NICU. Transporting the mother afterward for postpartum care is beneficial, but financial barriers and lack of insurance provider coverage are problems in some areas. Parents of transported infants often describe the separation in terms of loss, and may experience a grief response, even when the condition of the infant is not serious.

The NICU environment can be challenging for parents. There are many rules to follow, and parents are still excluded in many NICUs from important activities such as nursing shift changes or multidisciplinary rounds. Parents may be asked to leave the NICU for procedures on their infants, or in open units to leave when procedures are necessary on other infants in the same area. Many parents report not feeling like their infant's parent until the infant is discharged home.[11]

Many of the barriers placed for parent participation in care are well-intentioned, such as concerns about safety of moving and handling ill infants, concerns about confidentiality, and concerns of protecting parents from stress of seeing procedures that may seem painful. There have been few carefully performed studies to determine relative risks and benefits to more active parental participation in care.

NICUs were historically designed to facilitate care providers, particularly nurses, caring for several infants. The need for efficiency of care providers led to the creation of large areas with little physical or environmental separation between bed spaces. Supportive space for parents was severely lacking, and private spaces for rooming in or for collaborative parent/provider care did not exist. One of the first demonstrations that direct parent care may be beneficial for premature infants during the intermediate or convalescent period before discharge was reported by Forsythe.[21] Infants cared for in living/sleeping units by their parents with a small group of consistent neonatal nurses had decreased length of hospital stay, fewer rehospitalizations, reduced visits to emergency departments, and reduced parental anxiety. Increasing understanding of the importance of environmental factors on care outcomes for premature or sick infants has led to rethinking the design standards for NICUs. Standards include recommendations for lighting and noise levels and the importance of being able to cycle light and to individualize the environment based on the needs of the infant and family. New NICUs are being built with at least some, if not all, beds in individual rooms.[64]

Interventions for Premature or Sick Infants and Their Parents

Adverse outcomes of infants requiring intensive care, particularly infants born prematurely, continue to be frequent, despite improvements in survival. Unexplained variation in outcomes among centers after careful risk adjustment has been seen for neurodevelopmental outcomes as it has for in-hospital morbidity and mortality.[61] Reasons for variations are difficult to define because there may be unadjusted variation in the patient populations and differences in care practices. Most carefully conducted trials in neonatology have been for medical interventions. Studying care of parents, alterations in the environment, and therapeutic interventions that are difficult to blind is much more difficult, and consequently efficacy of many proposed interventions for developmental and family support has not gained full acceptance based on lack of strong evidence. Several promising new ideas and systematic practices have solid theoretical benefits and growing evidence for efficacy. More is needed.

Melnyk and associates,[40] in a randomized, controlled study, tested the effect of an educational-behavioral intervention program on outcomes of premature infants 26 to 34 weeks' gestational age or weighing less than 2500 g and their mothers. The program was comprised of four intervention sessions, three of which were during the hospital stay. The fourth occurred 1 week after discharge home. The sessions contained information on infant behavior and parent roles, development of premature infants and recognizing infant stress and cues that signal readiness for interaction, transition to home and advice about forming a strong parent-infant relationship, and anticipatory guidance about premature development. The sessions contained suggested activities for parents to reinforce the lessons. Parents of control infants received written and audiotaped materials at the same intervals, but containing routine information about hospital procedures, information given to all parents at discharge, and postdischarge information about immunizations.

The results of the Melnyk study[40] were impressive. Mothers in the intervention group exhibited significantly less stress while their infant was in intensive care, and less depression and anxiety at 2 months corrected age compared with mothers in the control group. Fathers and mothers in the intervention group were rated by observers blinded to study assignment as more positive in interactions with their infants. Mothers and fathers also reported stronger beliefs about their parental role and were more informed of behaviors and characteristics to expect of their infants. Infants in the intervention group had a 3.9-day shorter length of stay (mean 35.29 days versus 39.19 days) compared with control infants. This study strongly suggests that problems of parenting associated with intensive care may be ameliorated with simple interventions. In addition, provision of mental health services for selected families and staff in the NICU setting, offers an important adjunct to routine care in this difficult setting.[23a]

INDIVIDUALIZED DEVELOPMENTAL CARE

Premature infants are at risk of numerous morbidities related to the immaturity of multiple organ systems, including the brain. An unfavorable physical or care environment could exacerbate these morbidities. Modification of practices or the environment could reduce the adverse effects. Many approaches to care have been included under the category of "developmental care." Examples are modification of external sensory stimuli, such as noise, light, excessive handling, and pain; swaddling and positioning; massage; promoting interactions based on infant cues; and others. Als and colleagues[3] proposed a systematic approach that combines many evaluation and intervention practices: the Newborn Individualized Developmental Care and Assessment Program (NIDCAP). (See also Chapter 30, Part 2, and Chapter 43.)

The NIDCAP approach involves an assessment of each infant on a daily basis by trained observers, which is used in conjunction with the parents and direct care providers to individualize care based on various infant behaviors, including autonomic, motor, and state behaviors. There have now been five randomized, controlled trials of NIDCAP (reviewed in Cochrane reviews).[57] The meta-analysis shows that there is a benefit in the study groups compared with controls in reduced incidence of moderate to severe chronic lung disease and necrotizing enterocolitis, and improved family and neurodevelopmental outcomes at 6 months.

Als and colleagues[4] also reported that 28- to 33-week gestation premature infants provided NIDCAP intervention evaluated at 2 weeks of age, corrected for prematurity, have better neurobehavioral function and correlated MRI structural differences. The study infants compared with controls had increased coherence between frontal and a broad spectrum of mainly occipital brain regions, a higher relative anisotropy in the left internal capsule, and a trend for the right internal capsule and frontal white matter.

Because the NIDCAP trials have involved a system of intervention, it is difficult to sort out which of the multiple practices are most important. Other trials of individual developmental interventions have been inconclusive, and most are limited by poor study design and inadequate sample size or long-term follow-up.

The theoretical framework behind family-centered, developmentally supportive care (NIDCAP) is endorsed by research from several scientific fields, including neuroscience, developmental and family psychology, medicine, and nursing. The introduction of NIDCAP involves a considerable investment at all levels of the organization, however. NIDCAP requires some physical changes in the NICU and substantial educational efforts and changes in the practice of care. Shortcomings in design and methods in the reviewed studies hamper far-reaching claims of the effectiveness of the method. Scientific grounds for assessing the effects of NIDCAP would be substantially enhanced by a sufficiently comprehensive study with extended follow-up and a clear focus on a few important outcome variables. In Holland, providing NIDCAP to preterm infants born at less than 32 weeks' gestational age in a system with regionalized NICUs had no effect on their neurodevelopment at 1 and 2 years of age.[39] Wallin and Eriksson[62] commented that "Despite promising findings, primarily on cognitive and motor development, the scientific evidence on the effects of NIDCAP is limited."

KANGAROO BABY CARE

Kangaroo baby care, also referred to as *skin-skin contact,* originated as a means of keeping at-risk infants warm in settings where there was no technology for maintaining temperature in newborn high-risk infants. Subsequent studies have indicated potential benefits in promoting breast feeding, establishing parent-child attachment, and promoting neurodevelopment. (See also Chapter 43.)

"Kangaroo" contact may be the first time some parents of babies requiring specialized medical and nursing care feel close to their infant and feel that the infant is truly theirs.

Skin-to-skin care may be useful in helping parents develop a closer tie to their infant. Properly detailed observations have noted that the infant's heart rate, temperature, and respiratory rate are stable with kangaroo care, and there is no increase in apnea during the daily 1- to 2½ -hour experience.[65] In kangaroo care, the premature infant has long periods of deep sleep. Brain wave patterns show two to four periods of "delta brush/hour" not seen in the incubator. Delta brush occurs with synapse formation. Additionally, significant increases in milk output and an increase in the success of lactation have been documented with skin-to-skin care.

Feldman and colleagues[15-17] described a valuable study of kangaroo care in Israel with a 6-month follow-up period. The study comprised 146 premature infants weighing 530 to 1720 g matched for sex, birthweight, age, and medical risk. All families were middle-class. Seventy-three infants received kangaroo care, and 73 were controls. At 31 to 34 weeks, the kangaroo care group received at least 1 hour per day for 2 weeks of kangaroo care; they were examined at 37 weeks, 3 months, and 6 months of age. At 37 weeks, kangaroo care mothers showed a significantly more positive affect, more touch, more visual regard, and better adaptation to infant cues, and they reported less depression and perceived the infant as less abnormal. The kangaroo care infants showed significantly more alertness, less gaze aversion, longer quiet sleep and alert wakefulness, and less time in active sleep.

Kangaroo care infants showed more rapid maturation of vagal tone between 32 and 37 weeks, and more mature neurodevelopmental profiles with greater development of habituation and orientation. At 3 months, mothers and fathers were more sensitive to the infants and provided a better home environment. Kangaroo care infants had higher thresholds for negative emotionality and more efficient arousal modulation while attending to increasingly complex stimuli. At 6 months, kangaroo care infants had longer duration and shorter latency to mother-infant shared attention and infant-sustained exploration in a toy session. Kangaroo care mothers were more sensitive and warm in their interactions, and infants had higher scores on the Bayley Mental Developmental Index (kangaroo care mean 96.3, controls mean 91.8) and the Psychomotor Developmental Index (kangaroo care mean 85.5, controls mean 80.5). The authors underscore the importance of the role of early skin-to-skin contact of the mother in the maturation of the infant's physiologic, emotional, and cognitive regulatory capacities.

Kangaroo care should be considered for every premature infant at the critical time of 31 to 34 weeks. Additional research is needed to evaluate risks and benefits to more immature infants and infants requiring highly technical care, such as conventional or high frequency mechanical ventilation.

FAMILY-CENTERED CARE IN THE NEONATAL INTENSIVE CARE UNIT

The field of neonatal intensive care has changed dramatically in the past few decades. Significant scientific and concurrent technological advances have resulted in decreases in premature neonatal morbidity and mortality. The growing body of research on the psychosocial sequelae of premature birth has engendered widespread appreciation of the impact of the neonatal intensive care experience on the entire family.

Premature birth is often an unexpected crisis, and it compounds the stressors of a normal pregnancy. Infants admitted to an intensive care nursery face significant problems that have the potential to affect family functioning adversely. Parents of these infants are confronted with many challenges, including the unexpected appearance and behavior of their infant, physical separation from their infant, difficulties in obtaining accurate information about their infant's condition, a bewildering number of care providers, inability to protect their infant from pain, and, frequently, financial concerns.

In 1992, a group of parents knowledgeable about the NICU from personal experience were invited to meet with a group of neonatal professionals to address problems identified by the NICU parents and to explore possible solutions. "The Principles for Family-Centered Neonatal Care," a document describing the necessary elements of family-centered neonatal care, was published after the conference.[23] Many of the principles laid out in the original document can be found in national and regional organizational statements recommending care that encourages family presence and participation.[1,26]

The principles of family-centered care are remarkably simple, but often difficult to achieve. Family-centered neonatal intensive care is an approach to care based on the recognition that the family is the most consistent and influential force in the growth and development of the child. It involves creating mutually beneficial partnerships between families and providers for the planning, delivery, and evaluation of health care.

Successful integration of family-centered care within NICUs requires a comprehensive approach. Family-centered care must be grounded in the vision and philosophy of the organization, supported by the physical design and environment, and adhered to daily in policies and programs consistent with the vision. Multicenter, multidisciplinary quality improvement initiatives have outlined practices and developed tools that may be useful in implementing changes.[13,51]

Some practices that may be considered for implementing family-centered care include the following:

- The unit vision and philosophy should clearly articulate the principles of family-centered care.
- Leaders at the center level and the unit level should clearly promote the principles of family-centered care.
- Parents are not "visitors." Rather, parents should be treated as essential components of the care team. Policies should be revised to reflect this view. "Visiting Policies" should be revised to address nonparent family members and friends; policies related to parents should be more appropriately addressed as participation in care.
- Neonatal care is multidisciplinary and based on mutual respect among providers for their roles and expertise. Parents

are integral to care and should be encouraged to participate in patient care rounds, communication with personnel at the change of shifts, and in the bedside care of their infant. Parents should have access to information in their infant's medical record, and many units have initiated parent documentation into the record.

- The physical environment should provide for the needs of parents. Parents' needs for accessing information, rest, nutrition, privacy, childcare for siblings, and support for their infants by breast milk pumping are often inadequately addressed. Standards for support of families are available.[64]
- Nursery staff should receive the support they need to provide optimal family-centered care. This support includes an environment that allows staff respite to meet their own needs and ongoing education and resources to support family-centered care.
- Families should be incorporated at various levels as advisors. The perspective of experienced families should be integral to the unit administrative activities. These could include parents as teachers during orientation and continuing education of staff, and parent advisory committees to collaborate in planning of new policies or space and ongoing quality improvement activities.

INFANTS WITH CONGENITAL MALFORMATIONS

The birth of an infant with a congenital malformation presents complex challenges to the care team and to the infant's family. Despite the numerous infants with congenital anomalies, understanding of how parents develop an attachment to a malformed child remains incomplete. The process frequently begins when routine antenatal screening, including imaging, reveals a likely problem. Although previous investigators agreed that the child's birth often precipitates major family stress, few have described the process of family adaptation during the infant's first year of life. A major advance was the conceptualization of parental reactions by Solnit and coworkers.[56] They emphasized that a significant aspect of adaptation is the necessity for parents to mourn the loss of the normal child they had expected. Other observers have noted the pathologic aspects of family reactions. Less attention has been given to the more adaptive aspects of parental attachments to children with malformations.

Parental reactions to the birth of a child with a congenital malformation seem to follow a predictable course. For most parents, initial shock, disbelief, and a period of intense emotional upset, including sadness, anger, and anxiety, are followed by a gradual adaptation, marked by a lessening of intense anxiety and emotional reactions (Fig. 33-4). This adaptation is characterized by an increased satisfaction with the ability to care for the infant. These stages in parental reactions are similar to the stages reported in other crisis situations, such as with terminally ill children. The shock, disbelief, and denial reported by many parents seem to form an understandable attempt to escape the traumatic news of the infant's malformation, so discrepant with usual parental expectations for a normal newborn.[12]

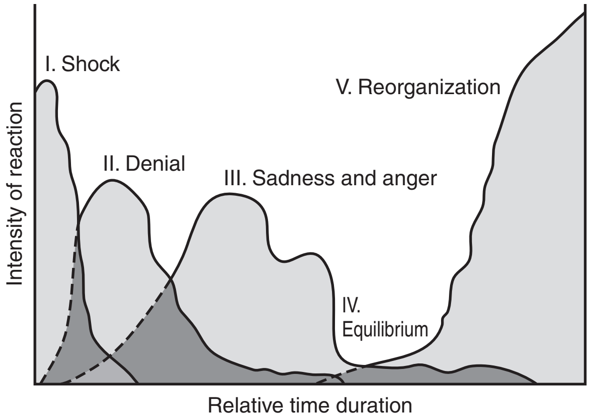

Figure 33–4. Hypothetical model of a normal sequence of parental reactions to the birth of a malformed infant. *(Modified from Drotar D et al: The adaptation of parents to the birth of an infant with a congenital malformation: a hypothetical model,* Pediatrics *56:710, 1975. Copyright American Academy of Pediatrics, 1975. Reproduced by permission of* Pediatrics.*)*

In addition to mourning the loss of her expected, normal infant, the mother must become attached to her living, child with physical problems. The sequence of parental reactions to the birth of a infant with a malformation differs from that after the death of a child in yet another respect, however. The mourning or grief work apparently does not occur in the usual manner because of the complex issues raised by continuation of the child's life and the demands of physical care. The parents' sadness, which is important initially in their relationship with their child, diminishes in most instances when the parents take over the physical care. Most parents reach a point at which they are able to care adequately for their children and cope effectively with disrupting feelings of sadness and anger. Not all parents reach the point of complete resolution; Olshansky[44] has described chronic sorrow that envelops the family of a mentally defective infant. The mother's initiation of the relationship with her child is a major step in the reduction of anxiety and emotional upset associated with the trauma of the birth. As happens with normal children, the mother's initial experience with her infant seems to release positive feelings that aid the mother-child relationship after the stresses associated with the news of the child's anomaly have abated and, in many instances, when mother and child are able to be reunited after separation.

Interventions for Parents of Malformed Infants

To help parents deal with the situation of having an infant with a congenital malformation, the following interventions are suggested:

- The infant should be left with the mother for the first 2 or 3 days, if medically feasible. If the infant is rushed to the hospital where special surgery is to be performed eventually, the mother does not have enough opportunity to become attached to the infant. Even if the surgery is required immediately, as for bowel obstruction, it is best to bring the infant to the mother first, allowing her to touch and handle the infant and to point out to her how normal he or she is in all other respects.

- The mental picture of the anomaly held by parents before seeing the infant is often far more alarming than the actual problem. Any delay during which the parents suspect that a problem may exist greatly heightens their anxiety, and they may imagine the worst; the infant should be brought to both parents when they are together as soon after delivery as possible.[41]
- Arrangements should be made for the father to stay with the mother in her room on the maternity division. This opportunity to support each other is highly beneficial. The clinician should use the process of early crisis intervention, meeting several times with the parents, regardless of whether the father stays in the hospital with the mother. During these discussions, the clinician should ask the mother how she is doing, how she feels her husband or partner is doing, and how the father feels about the infant. Then the clinician should reverse the questions and ask the father how he is doing and how he thinks the mother is progressing. The hope is that they will think not only about their own reactions, but will begin to consider each other as well.
- Parents should not be given tranquilizers. These tend to blunt their responses and slow their adaptation to the problem. A small dose of a sedative at night is often helpful, however.
- Experience has shown that parents who initially adapt reasonably well often ask many questions and sometimes seem to be almost overinvolved in clinical care.
- Many anomalies are very frustrating, not only to the parents but also to the physicians and nurses. The physician may be tempted to withdraw from the parents and their infant. The many questions asked by the parent who is trying to understand the problem can be very frustrating for the physician. The parent often seems to forget and asks the same questions repeatedly.
- Each parent may move through the process of shock, denial, anger, guilt, and adaptation at a different pace, so the two parents may not be synchronized. If they are unable to talk with each other about the infant, their relationship may be severely disrupted. It is extremely important to move at the parents' pace. Moving too quickly runs the risk of losing the parents along the way. It is essential to ask the parents how they view their infant.

SUMMARY

Because the newborn completely depends on the parents for survival and optimal development, it is essential to understand the process of bonding as it develops from the first moments after the child is born. Although we have only begun to understand this complex phenomenon, individuals responsible for the care of mothers and infants should evaluate hospital procedures and ensure early, sustained mother-infant contact. Care practices should be developed that promote contact of the mother and father with their infant and help them learn and explore the wide range of sensory and motor responses of their newborn infant, whether healthy or requiring intensive care.

CHAPTER 34

The Late Preterm Infant

Ashwin Ramachandrappa and Lucky Jain

Births between $34\frac{0}{7}$ and $36\frac{6}{7}$ weeks' gestation (referred to herein as *late preterm births*), account for a significant proportion of preterm births in North America and elsewhere. These infants are larger than the usual premature infant, and they are generally passed off as mature infants, but they often manifest signs of physiologic immaturity or delayed transition in the neonatal period. Several studies have documented the high incidence of neonatal complications leading to neonatal intensive care unit (NICU) admissions in these infants.[11,20,59] They have a higher incidence of transient tachypnea of the newborn (TTN),[47,73] respiratory distress syndrome (RDS),[11,73] persistent pulmonary hypertension of the newborn (PPHN),[59] respiratory failure, jaundice, temperature regulation problems, hypoglycemia, and feeding difficulties than term infants.[16,19,22]

Concern about higher morbidity in late preterm infants has led to numerous publications with largely the same conclusions: Late preterm infants are more prone to problems related to delayed transition and overall immaturity, and they should be treated differently from their more mature term counterparts.[*] These observations have led to greater attention being paid to tracking short-term morbidity, health care costs, hospital stays, and issues such as rehospitalization.[4,20] Nearly three out of four preterm births occur at late preterm gestational ages, and this number is increasing.[45] Although the problem seems to be widespread, similar estimates from other nations are not readily available. Evidence is emerging that the increase in the late preterm birth rate is not limited to the United States alone, but is a worldwide phenomenon, although reported rates seem to be quite variable. The late preterm birth rate was estimated to be 4.4% to 4.9% in Canada in the 1990s.[38] In Denmark, moderately preterm births (32 to 36 weeks) constituted 5.36% of all singleton live births, and this rate has increased by 22% from 1995-2005. A Brazilian study estimated the late preterm birth rate to be 10.8% in that country.[60]

DEFINITION

Preterm infants have been aptly and clearly classified for many decades. The World Health Assembly in 1948 described preterm infants as infants weighing less than 2500 g or being less than 37 weeks' gestation. In 1950, the World Health Organization revised this definition, identifying all infants born before 37 completed weeks' gestation (259th day), counting from the first day of the last menstrual period, as preterm infants.[55] The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (ACOG) agree with this definition.[2]

Although *preterm, term,* and *post-term* have been clearly defined according to the week and day of gestation by the World Health Organization, American Academy of Pediatrics, and American College of Obstetrics & Gynecology, not all subgroups within the preterm gestation are well defined. There is less ambiguity about infants less than 32 weeks' gestation in the literature, being defined as *very preterm* if less than 32 weeks' gestation, and *extremely preterm* if less than 28 weeks' gestation, but no clear definition existed for infants of 32 to 37 weeks' gestation. These infants were known by several different names, including *moderately preterm, mildly preterm, minimally preterm, marginally preterm,* and *near-term*. These near-term infants have been inconsistently defined in the literature as 34 to 36 weeks' gestation, 35 to 37 weeks' gestation, and 35 to $36\frac{6}{7}$ weeks' gestation.

To clarify and to place a greater emphasis on the fact that these near-term infants have a greater risk of morbidity and mortality than term infants, an expert panel at a workshop convened by the National Institute of Child Health and Human Development of the National Institutes of Health in July 2005 recommended that births between 34 completed weeks ($34\frac{0}{7}$ weeks or day 239) and less than 37 completed weeks ($36\frac{6}{7}$ weeks or day 259) of gestation be referred to as *late preterm* infants (Fig. 34-1).[56] Several factors led to this definition; 34 weeks is considered a maturational milestone in obstetric practice after which surfactant is usually present in the lungs and is often used as a cutoff for giving antenatal steroids. Because there is no such thing as a normal preterm

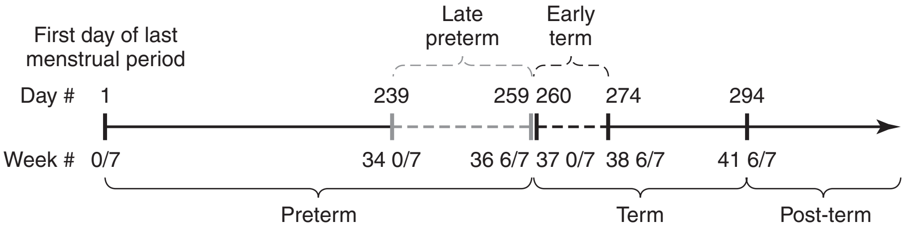

Figure 34–1. Definition of *late preterm* and *early term*. (*Redrawn from Engle WA, Kominiarek MA: Late preterm infants, early term infants, and timing of elective deliveries,* Clin Perinatol *35:325, 2008.)*

infant, and the name *near-term* might imply that these infants are as healthy as term infants, use of terms such as *near-term* was discontinued. More recently, data have shown that term infants born at 37 weeks' and 38 weeks' gestation have higher morbidity and mortality than infants born at 39 weeks' gestation.[27,42,47,63] Engle and Kominiarek[17] suggested identifying infants between 37 completed weeks' gestation (37⁰⁄₇ weeks or day 260) and 38 completed weeks' gestation (38⁶⁄₇ weeks or day 274) as *early term* infants.

EPIDEMIOLOGY AND TRENDS

In the United States, there were 4,138,349 live births in 2005, of which 12.7%, or approximately 525,000, were preterm.[44] Late preterm infants constituted 72% (approximately 375,000) of all preterm births. Preterm births have increased by nearly 20% since 1990, but the late preterm birth rate has shown a much bigger increase of 25% since 1990 (Fig. 34-2). Looking at only singleton births (because multiple gestations are prone to preterm birth), preterm births <34 weeks have declined 0.7% since 1990, but late preterm births have increased by 16%; looking at all births, the very preterm birth rate has shown a modest increase of 16%, whereas the late preterm birth rate has increased by 44%.[44] Despite advances in obstetric/neonatal medicine over the last two decades, late preterm infants are primarily responsible for the entire increase in the preterm birth rate.

Non-Hispanic black infants have nearly 1.5 times the late preterm birth rate than non-Hispanic white infants. The late preterm birth rate was 10.9% for singleton non-Hispanic black infants, 8.1% for Hispanic infants, and 7.4% for non-Hispanic white infants. During 1990-2005, singleton late preterm birth rates increased by 35% for non-Hispanic whites and 10% for Hispanics; for non-Hispanic blacks, the rate declined during 1990-2000, but has increased by 7% since 2000 (Fig. 34-3). Despite having the lowest rate of late preterm births, non-Hispanic white infants had the largest increase (35%) in late preterm births during 1990-2005.[44] Because non-Hispanic whites are responsible for most U.S. births, the overall increase in preterm birth rate in the United States can be explained largely by an increase in late preterm births among non-Hispanic white infants.[13,44]

A trend toward earlier deliveries is also seen at what is traditionally referred to as term gestation (≥37 weeks' gestation). Singleton births at 40 weeks and greater have declined by 29% since 1990, and births at 37 to 39 weeks have increased by 31% over the same time period.[44] In a study that used national birthing trends from 1992-2002, Davidoff and colleagues[13] identified an overall shift of gestational length to 39 weeks from 40 weeks (Fig. 34-4) among all groups,

Figure 34–2. Figure 34–4. Shifting distribution of gestational age among spontaneous singleton live births, United States, 1992, 1997, and 2002. *(From Davidoff MJ et al: Changes in the gestational age distribution among U.S. singleton births: impact on rates of late preterm birth, 1992 to 2002,* Semin Perinatol *30:8, 2006.)*

including spontaneous births, induced births, and birth with medical interventions (e.g., cesarean section). The rates of cesarean sections and inductions have increased during the same time period; this continued trend toward delivery at earlier gestational ages is expected to increase births at early term gestations (37 to 39 weeks' gestation) and eventually late preterm births. Earlier studies indicated that late preterm infants have survival rates within 1% of term infants,[28] but there is mounting evidence to show that late preterm infants have significantly higher morbidity compared with term infants.

ETIOLOGY

The etiology of prematurity is complex and multifactorial, and although known clinical entities such as preeclampsia and premature rupture of membranes (PROM) are significant contributors to preterm births, several other causes have been implicated in the increase in the late preterm birth rate (Box 34-1). Data from Columbia University in New York City show that nearly 42% of late preterm deliveries were spontaneous (PROM or preterm labor), 28% were indicated because of maternal or fetal conditions, and nearly 30% were elective deliveries (unpublished data).

Medical Interventions and Iatrogenic Causes

Cesarean section rates have dramatically increased in the United States and worldwide, increasing from a low of 5% in 1970 to 31% in 2006.[26] Among the many reasons cited for this increase are increased fetal surveillance and interventions, the increasing age of women giving birth, a greater number of multiple gestations from fertility treatments, obesity, and heightened concerns of physicians and mothers about the risks of vaginal birth. In 2006, a national consensus conference coined a new term for cesarean deliveries for which no medical indication could be found and where maternal choice was the leading factor—*cesarean delivery on maternal request*.

Although the exact number of such deliveries is hard to track, it is believed that 10% of cesarean sections may be performed at maternal request.[57] Declercq and colleagues[14] examined demographic and medical risk factors from 1991-2002, and found no association between changes in the maternal risk profile and the observed shifts in the primary cesarean section rates, implying that changes in maternal characteristics are not responsible for the increasing rate of cesarean sections. Davidoff and colleagues,[13] looking at birth certificate data from 1992-2002, showed that all categories of live births have had an increase in late preterm (34 to 36 weeks' gestation) and early term (37 to 39 weeks' gestation) birth rate. Although spontaneous births and births from PROM declined during this period, births from medical interventions increased, with cesarean section accounting for most of the medical intervention group.

Although elective cesarean sections are discouraged before 39 weeks' gestation, a study by Tita and associates[66] from the National Institute of Child Health and Human Development–Maternal-Fetal Medicine Units' Network found that of the 24,077 elective repeat cesarean sections at term gestation (from 19 centers during 1999-2002), nearly 36% were performed before 39 weeks. Births at 37 and 38 weeks had greater than 1.5 times the odds of death or complications, including respiratory compromise, hypoglycemia, sepsis, and admission to the NICU (Table 34-1).[66] Induction rates have also increased with cesarean section rates, and there was a shift toward earlier gestations in both groups.[13] In 2005, 22% of all singleton live births were induced. Of those, late preterm and term births had the largest increase in induction rates. Overall, the induction rates for late preterm births have increased 130% since 1990, and these rates have increased 175% for the early term group.[44] Although medically indicated interventions have led to a decrease in the number of stillbirths, we do not know how much this has contributed to the increase in preterm birth rate, and if the gains realized in preventing stillbirths are offset by increased NICU admissions and complications associated with prematurity (Fig. 34-5).

Some evidence suggests that 2.5% to 18% of live births are delivered by cesarean section on maternal request.[48,51] Other studies disagree,[15,46] claiming that the increasing cesarean section rates stem from the changing practice standards of medical professionals and their willingness to perform cesarean sections because of the perceived safety and protection from malpractice litigation. Further prospective studies are required to quantify how much of the increase in late preterm births is due to necessary medical interventions, and how much can be attributed to cesarean section by physician or maternal request.

BOX 34–1 Etiology of Late Preterm Births

IDIOPATHIC
Preterm labor
PROM
Preeclampsia

MEDICAL INTERVENTIONS AND IATROGENIC
Increased medical surveillance and interventions
Cesarean or planned induction of labor. Medical indications:

- Abnormal presentation, abnormal placentation, maternal or fetal conditions (e.g., PROM without labor, fetal hydrocephalus)
- Repeat cesarean section

Cesarean or planned induction of labor. No medical indication:

- Induction of labor or cesarean section on maternal request
- Fear of fetal and neonatal risks with vaginal delivery
  Increased rate of stillbirths beginning at 39 weeks' gestation
  Hypoxic-ischemic encephalopathy, brachial plexus, and other birth traumas
- Fear of maternal risks with vaginal delivery
  Risk for genital tract, anus, and perineal injury and sexual dysfunction
  Perception that cesarean delivery is "easier" and "less stressful" than vaginal delivery
  Fear of the second stage and having to "push the baby out"
- Maternal willingness to accept risk on behalf of the infant
- Convenience for mother and family

GESTATIONAL AGE ASSESSMENT AND OBSTETRIC PRACTICE GUIDELINES
Inaccurate gestational age assessment during elective deliveries
Maternal obesity
Presumption of fetal maturity at 34 weeks' gestation
Decreasing gestational age criteria for inductions and increased rate of stillbirths beginning at 39 weeks' gestation

ADVANCED MATERNAL AGE, ASSISTED REPRODUCTIVE TECHNOLOGIES, AND MULTIPLE BIRTHS
Increase in multifetal pregnancies
Delayed childbearing and increased risk for prematurity
Use of assisted reproductive technologies (multifetal pregnancies) and increased risk for complications associated with premature delivery (e.g., preeclampsia, diabetes)

PHYSICIAN PRACTICE PATTERNS AND RISK/BENEFIT DETERMINATION
Convenience
Liability

PROM, premature rupture of membranes.
Adapted from Engle WA, Kominiarek MA: Late preterm infants, early term infants, and timing of elective deliveries, *Clin Perinatol* 35:325, 2008.

Gestational Age Assessment and Obstetric Practice Guidelines

Gestational age measurement is an inexact science; the methods currently used, such as the Naegele rule, which assesses gestational age from the first day of the last menstrual period, and ultrasound at 20 weeks' gestation, are accurate only to ± 1 to 2 weeks' gestational age. Combined with the fact that developmental variability exists during fetal maturation, and conditions such as maternal obesity and PROM can cause an overestimation or underestimation of gestational age, the task of accurate gestational age prediction is even more challenging. In an attempt to reduce mortality among post-term gestations, ACOG in 1989 recommended induction of labor at 43 weeks.[3] The Society of Obstetricians and Gynecologists of Canada later recommended induction at 41 weeks.[12] ACOG more recently issued guidelines that cesarean delivery or induction on maternal request should not be performed before 39 weeks' gestation or without evidence of lung maturity.[1] This gradual shift toward lower gestational age along with the inaccuracies of gestational age measurement might have led to the increasing proportions of late preterm births.

Tocolysis and antenatal steroids are routinely recommended only for women at less than 34 weeks' gestation because infants born at 34 weeks' gestation and beyond are believed to have mortality rates similar to that of term infants.[17] More recent studies have shown, however, that infants born at 34 weeks' gestation are at 50% increased risk for requiring intensive care,[18,21,31,69] and late preterm infants have increased morbidity, including long-term morbidities such as behavioral and developmental delay.[10] This idea of a magical cutoff at 34 weeks when the fetus becomes mature compared with just a few days prior needs to be revisited in light of new evidence.

Use of intrapartum fetal monitoring and prenatal ultrasound has been increasing over the years, from a rate of 68% and 48% respectively in 1989 to 85% and 67% in 2003.[17] Prenatal ultrasound can lead to an overestimation of gestational age in conditions associated with fetal macrosomia, such as obesity and gestational diabetes, both of which have increased rapidly in the last decade. There is the possibility of earlier intervention (induction or elective cesarean section) when ultrasound estimates are used to guide the management plan.[55] Although fetal surveillance is designed to reduce adverse neonatal outcome, when coupled with antenatal tests with poor positive predictive value (biophysical profile, nonstress test) it may inadvertently increase medical interventions, with a resultant increase in late preterm and early term birth rates.[17]

TABLE 34–1 Odds Ratios* for Adverse Neonatal Outcomes According to Completed Week of Gestation at Delivery

Outcome†	37 wk	38 wk	39 wk	40 wk
Any adverse outcome or death	2.1 (1.7-2.5)	1.5 (1.3-1.7)	Reference	0.9 (0.7-1.1)
Adverse respiratory outcome				
RDS	4.2 (2.7-6.6)	2.1 (1.5-2.9)	Reference	1.1 (0.6-2.0)
TTN	1.8 (1.2-2.5)	1.5 (1.2-1.9)	Reference	0.9 (0.6-1.3)
RDS or TTN	2.5 (1.9-3.3)	1.7 (1.4-2.1)	Reference	0.9 (0.6-1.2)
Admission to NICU	2.3 (1.9-3.0)	1.5 (1.3-1.7)	Reference	0.8 (0.6-1.0)
Newborn sepsis‡	2.9 (2.1-4.0)	1.7 (1.4-2.2)	Reference	1.0 (0.7-1.5)
Treated hypoglycemia	3.3 (1.9-5.7)	1.3 (0.8-2.0)	Reference	1.2 (0.6-2.4)
Hospitalization ≥5 days	2.7 (2.0-3.5)	1.8 (1.5-2.2)	Reference	1.0 (0.8-1.4)

*Odds ratio (95% confidence interval).

†All outcomes are adjusted for maternal age (as a continuous variable), race or ethnic group, number of previous cesarean deliveries, marital status, payer, smoking status, and presence or absence of diet-controlled gestational diabetes mellitus.

‡Newborn sepsis included suspected infections (with clinical findings suggesting infection) and proven infections.

NICU, neonatal intensive care unit; RDS, respiratory distress syndrome; TTN, transient tachypnea of the newborn.

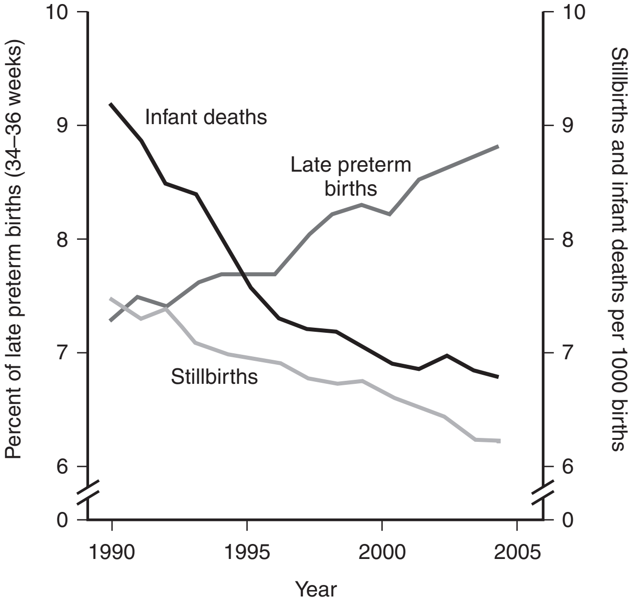

Figure 34–5. Trends in late preterm birth, stillbirth, and infant mortality, United States, 1990-2004. *Right axis* shows trends in stillbirth and infant mortality rates. *Left axis* shows trends in late preterm births (34-36 weeks). Late preterm birth rates are shown per 100 live births; stillbirth rates, per 1000 total births; and infant death rates, per 1000 live births. *(From Ananth CV et al: Characterizing risk profiles of infants who are delivered at late preterm gestations: does it matter?* Am J Obstet Gynecol *199:329, 2008.)*

Advanced Maternal Age, Assisted Reproductive Technologies, and Multiple Births

More women are now choosing to have children at a later age; it is well known that preterm birth is more prevalent among women with advanced maternal age. Women older than 35 years old also have nearly twice the rate of cesarean section than women 20 to 24 years old. Increasing numbers of women are also seeking assisted reproductive technologies (ART); 38,910 women delivered infants through ART in 2005 (two times the 1996 rate), and more than 50% of these women were older than 35 years.[9] Of infants born by ART, 32% were of multiple gestations, and these births are more likely to be preterm.[9] From 1990-2005, the percentage of twins delivered preterm increased; late preterm births, which constituted 29% of these twin births in 1990, increased to 38% in 2005 (a 31% increase),[44] and twin births from ART make up a significant proportion of this group. Studies have shown that singleton births from ART are also more likely to be preterm.[5,9]

PATHOPHYSIOLOGY

It is surprising to some that late preterm infants who are large and chubby and do not look anything like their tiny preterm counterparts are at increased risk of medical complications related to prematurity. As their name implies, these infants are not term, however, and are prone to a host of clinical problems, including RDS, temperature instability, feeding difficulties, hypoglycemia, hyperbilirubinemia, apnea, late neonatal sepsis, prolonged hospital stay, and readmission.[18-20,56,73]

Thermoregulation

Thermoregulation in a newborn depends on the amount of brown adipose tissue, white adipose tissue, and body surface area (see also Chapter 30, part 1).[18,43,54] Nonshivering thermogenesis is controlled by the hypothalamic ventral medial nucleus through the sympathetic nervous system, which releases the neurotransmitter norepinephrine; this acts on the brown adipose tissue to liberate free fatty acids, which are eventually oxidized producing heat.[18,43,54] Late preterm infants have decreased stores of brown adipose tissue and the hormones responsible for brown fat metabolism, such as prolactin, norepinephrine, triiodothyronine, and cortisol, which peak at term gestation.[18,43] They are more likely to lose heat because of decreased amount of white adipose tissue and less insulation. Also, their smaller size leads to an increased ratio of surface area to body weight, losing heat readily to the environment.[18,43,54]

Feeding

Late preterm infants have poor coordination of sucking and swallowing because of neuronal immaturity, and have decreased oromotor tone, generating lower intraoral pressures during sucking.[18,36,54,56] Poor caloric intake and dehydration result with exacerbation of physiologic jaundice, leading to readmission to the hospital for dehydration and jaundice.[6,20] These infants also have decreased activity of hepatic uridine diphosphate glucuronyl transferase enzyme and increased enterohepatic circulation because of immature gastrointestinal function and motility. This decreased ability for hepatic uptake and conjugation puts late preterm infants at increased risk of elevated serum bilirubin levels, and jaundice is more prolonged, prevalent, and severe in these infants.[6] One study showed that infants born at 36 weeks' gestation have an eight times greater risk of developing a total serum bilirubin concentration greater than 20 mg/dL (>343 μmol/L) compared with infants born at 41 weeks or later.[52]

Glucose Homeostasis

The fetus gets a steady supply of glucose primarily by maternal transfer through the placenta. Immediately after birth, this constant supply of glucose is cut off, and the infant has to produce glucose primarily by hepatic glycogenolysis and gluconeogenesis.[25] The postnatal surge in catecholamines, glucagon, and corticosteroids plays an important role in maintaining euglycemic control. This increase in plasma concentrations of catecholamines causes a decline in circulating insulin concentrations and a subsequent surge in glucagon concentrations. Glucose-regulated insulin secretion by the pancreatic β cells is also immature, resulting in unregulated insulin production during hypoglycemia.[23] Late preterm infants are challenged to maintain euglycemia control secondary to developmentally immature hepatic enzyme systems for gluconeogenesis and glycogenolysis, hormonal dysregulation with inadequate adipose tissue lipolysis, and decreased hepatic glycogen stores that are depleted quickly after birth.[18,23,56]

Neurologic Immaturity

At 34 weeks' gestation, brain weight is only 65% of a 40-week term infant, and cerebral volume is 53% of a 40-week infant (Fig. 34-6).[7,36] The brain of a late preterm infant is still immature and continues to grow until 2 years of age, when it reaches 80% of adult brain volume. The cerebral cortex is still smooth compared with that of a term infant because the gyri and sulci are not fully formed on the cerebral cortex, and myelination and interneuronal connectivity are still incomplete in these infants. There is evidence that multiple insults during this critical phase of neuronal and glial maturation in these infants cause white and gray matter injury, particularly in the thalamic region and the periventricular white matter. All of this underscores the potential vulnerability of the late preterm infant to neuronal brain injury and poor developmental and long-term outcome.[36]

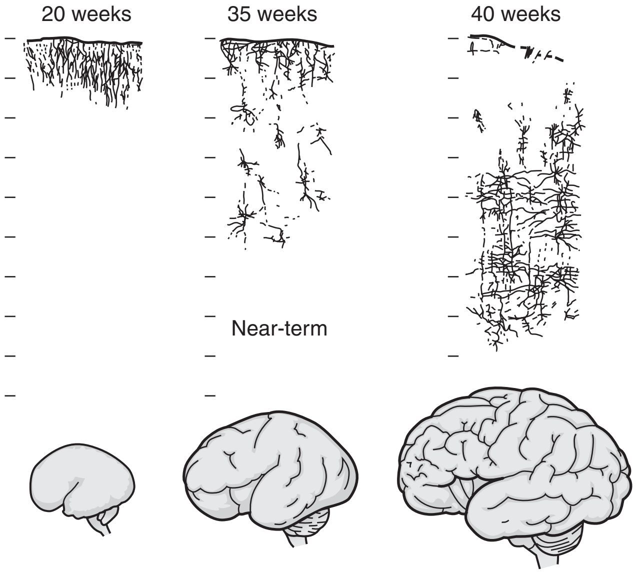

Figure 34–6. Development of the human cerebral cortex. The immaturity of the laminar position and dendritic arborization of neurons, as shown by Golgi drawings, in the cerebral cortex in a late preterm infant at 35 gestational weeks is striking compared with neurons at midgestation (20 weeks) and at term (40 weeks). Respiratory

Several studies have consistently shown that late preterm infants have higher respiratory morbidity and mortality, with increased risk of TTN, RDS, PPHN, and respiratory failure than term infants. Some studies have shown that late preterm infants and some early term infants born by cesarean section before the onset of labor have RDS despite having mature surfactant profiles. To understand this vulnerability for respiratory problems, one needs to understand the pathophysiology of fetal lung fluid secretion and clearance because it may play an important role in the development of RDS along with surfactant maturation.

Role of Fetal Lung Fluid Clearance in Neonatal Transition

Throughout much of gestation, fetal lungs actively secrete fluid into alveolar spaces via a chloride secretory mechanism that can be blocked by inhibitors of Na-K-2Cl cotransport.

This body of fluid plays a crucial role in lung development, providing a structural template that prevents collapse of the developing lung and promotes its growth. Conditions that interfere with normal production of lung liquid, such as pulmonary artery occlusion, diaphragmatic hernia, and uterine compression of the fetal thorax from chronic leak of amniotic fluid, are also known to inhibit lung growth.[34] The fetus is presented with a challenge at birth. Often at short notice, sometimes with no notice at all, the fetus is asked to clear the airspaces rapidly of the fluid that it has been secreting through much of the pregnancy. The lung epithelium is a key participant in this process, engineering the switch from placental to pulmonary gas exchange.[8,30]

For effective gas exchange to occur, alveolar spaces must be cleared of excess fluid, and pulmonary bloodflow must be increased to match *ventilation* with *perfusion*. Failure of either of these events can jeopardize neonatal transition and cause the infant to develop RDS. Clinicians are still far from completely understanding the mechanisms by which fetal lungs are able to clear excessive fluid at birth. It is clear, however, that traditional explanations that relied on “Starling forces” and “vaginal squeeze” can account for only a fraction of the fluid absorbed.[8,30] Amiloride-sensitive sodium transport by lung epithelia through epithelial sodium channels (ENaC) has emerged as a key event in the transepithelial movement of alveolar fluid.[8,33] Disruption of this process has been implicated in several disease states, including TTN and hyaline membrane disease. Using the fetal lamb model, several investigators have shown that much before the onset of spontaneous labor, the fetus begins preparation for extrauterine life by reducing the rate of lung fluid secretion and improving clearance.[30,34]

Developmental changes in transepithelial ion and fluid movement in the lung can be viewed as occurring in three distinct stages. In the first (fetal) stage, the lung epithelium remains in a secretory mode, relying on active chloride secretion via Cl^- channels and relatively low reabsorption activity of Na^+ channels. Why Na^+ channels remain inactive through much of fetal life is unclear. The second (transitional) stage involves a reversal in the direction of ion and water movement. A multitude of factors may be involved in this transition, including exposure of epithelial cells to an air interface and to high concentrations of steroids and cyclic nucleotides. This stage involves not only increased expression of Na^+ channels in the lung epithelia, but also possibly a switch from nonselective cation channels to highly selective Na^+ channels. The net increase in Na^+ movement into the cell can also cause a change in resting membrane potential leading to a slowing, and eventually a reversal of the direction, of Cl^- movement through Cl^- channels. The third and final (adult) stage represents lung epithelia with predominantly Na^+ reabsorption through Na^+ channels and possibly Cl^- reabsorption through Cl^- channels, with a fine balance between the activity of ion channels and tight junctions. Such an arrangement can help ensure adequate humidification of alveolar surface, while preventing excessive buildup of fluid.[34]

After birth, the remaining lung fluid is rapidly cleared by a two-step process (Fig. 34-7). The first step is passive movement

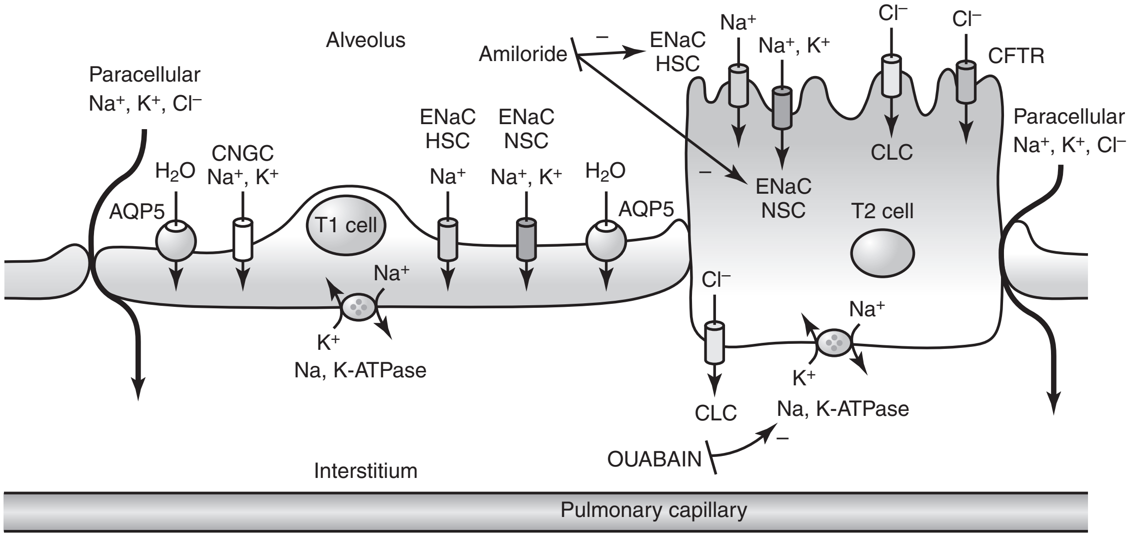

Figure 34–7. Epithelial sodium (Na) absorption in the fetal lung near birth. Na enters the cell through the apical surface of alveolar type I and alveolar type II cells via amiloride-sensitive epithelial Na channels (ENaC), both highly selective channels (HSC) and nonselective channels (NSC), and via cyclic nucleotide gated channels (seen only in angiotensin I cells). Electroneutrality is conserved with chloride movement through cystic fibrosis transmembrane conductance regulator (CFTR) or through chloride channels (CLC) in angiotensin I and angiotensin II cells, or paracellularly through tight junctions. The increase in cell Na stimulates Na,K-ATPase activity on the basolateral aspect of the cell membrane, which drives out three Na^+ ions in exchange for two K^+ ions, a process that can be blocked by the cardiac glycoside ouabain. If the net ion movement is from the apical surface to the interstitium, an osmotic gradient would be created, which would direct water transport in the same direction, either through aquaporins or by diffusion. CNGC, cyclic nucleotide-gated cation channel (*Redrawn from Jain L: Respiratory morbidity in late-preterm infants: prevention is better than cure!* Am J Perinatol *25:75-78, 2008.)*

of Na^+ from the lumen across the apical membrane into the cell through Na^+-permeable ion channels; the second step involves active extrusion of Na^+ from the cell across the basolateral membrane into the serosal space.[30] Epithelial Na^+ channels (ENaC), which regulate the first step, are rate limiting in this process. Hummler and coworkers[29] showed that inactivating the α-ENaC (α subunit of the epithelial Na^+ channel) leads to defective lung liquid clearance and premature death in mice. This is the first direct evidence that in vivo ENaC constitutes the limiting step for Na^+ absorption in epithelial cells of the lung. Studies in human neonates have also shown that immaturity of Na^+ transport mechanisms contribute to the development of TTN and RDS.[34]

ENaC expression is developmentally regulated with peak expression in the alveolar epithelium achieved only at term gestation[65]; late preterm infants are born with lower expression of ENaC, which reduces their ability to clear fetal lung fluid after birth. High doses of glucocorticoids have been shown to stimulate transcription of ENaC in several sodium-transporting epithelia and in the lung.[70] In the alveolar epithelia, glucocorticoids were found to induce lung sodium reabsorption in the late gestation fetal lung.[70] In addition to increasing transcription of sodium channel subunits, steroids increase the number of available channels by decreasing the rate at which membrane-associated channels are degraded, and increase the activity of existing channels. Glucocorticoids have also been shown to enhance the responsiveness of lungs to beta-adrenergic agents and thyroid hormones.[70] The enhanced sodium reabsorption induced by glucocorticoids can be blocked by amiloride, suggesting a role for ENaC.[34]

CLINICAL OUTCOMES

Morbidity in late preterm infants increases with decreasing gestational age; it is estimated to be nearly 52%, 26%, and 12% in 34-week, 35-week, and 36-week gestation infants.[63] Infants who were born at 34 weeks' gestation had 20 times (relative risk 20.6, 95% confidence interval [CI] 19.7 to 21.6) the risk for morbidity compared with infants who were born at 40 weeks' gestation; infants who were born at 35 weeks' and 36 weeks' gestation had 10 times (relative risk 10.2, 95% CI 9.7 to 10.8) and 5 times (relative risk 4.8, 95% CI 4.6 to 5.1) the risk for morbidity.[63] Because of their physiologic immaturity, nearly every organ system is affected in late preterm infants (Fig. 34-8). More recent data from the British Columbia Perinatal Database Registry show that late preterm infants had 4.4 times the respiratory morbidity and 5.2 times the neonatal infection rate than term infants. They also had increased length of hospital stay than term infants (142 hours versus 57 hours).[35] Mortality and morbidity are described in further detail in each physiologic system in this section.

Mortality

Kramer and colleagues,[38] using a large population-based cohort of linked birth/death certificate data of infants born in the United States and Canada, found relative risk for death from all causes in late preterm infants to be 2.9 (95% CI 2.8 to 3) and 4.5 (95% CI 4.0 to 5.0), with the corresponding etiologic fraction being 6.3% and 8% (etiologic fraction is the proportion of all cases of mortality that can be attributed to being born at late preterm gestation). The relative risk and etiologic fraction remained high even when deaths from congenital malformations were factored out.[38] Tomashek and coworkers,[67] using U.S. period-linked birth/infant death files for 1995-2002 to compare overall and cause-specific mortality rates between singleton late preterm infants and term infants, found that despite significant declines since 1995 in mortality rates for late preterm and term infants, infant mortality rates in 2002 were three times higher in late preterm infants than term infants (7.9 versus 2.4 deaths per 1000 live births); early (1-6 days), late (7-27 days), and postneonatal (28-365 days) mortality rates were 6, 3, and 2 times higher. During infancy, late preterm infants were approximately four times more likely than term infants to die of congenital malformations (leading cause); newborn bacterial sepsis; and complications of placenta, cord, and membranes.[67]

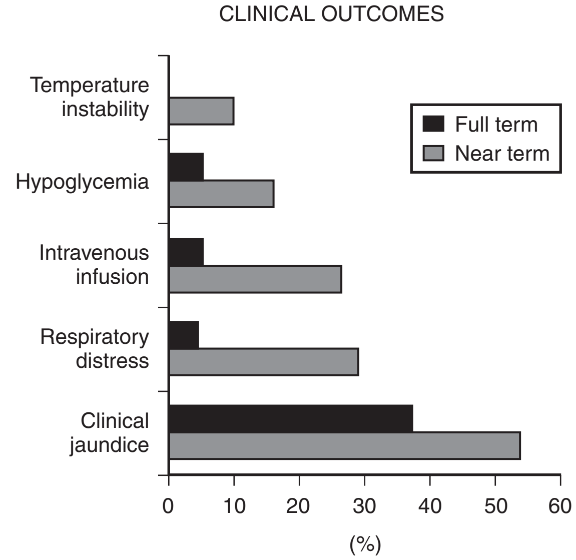

Figure 34–8. Graph of clinical outcomes in near-term (35-36$^{6}/_{7}$ weeks) and full-term infants as percentage of patients studied. *(From Wang ML et al: Clinical outcomes of near-term infants,* Pediatrics *114:372, 2004.)*

Young and associates,[74] in a large cohort from Utah, showed increasing mortality and relative risk of death for every decreasing week in gestational age less than 40 weeks (Table 34-2). In another study looking at a large cohort of 133,022 infants born at 34 to 40 weeks' gestation, McIntire and colleagues[47] found that neonatal mortality rates were significantly higher for late preterm infants (1.1, 1.5, and 0.5 per 1000 live births at 34 weeks, 35 weeks, and 36 weeks) compared with 0.2 per 1000 live births at 39 weeks ($P < .001$). Infants born only a few weeks before term gestation are at much greater risk of mortality; in 2005, the U.S. infant mortality rate for late preterm infants was high (7.3 versus 2.4 per 1000 live births in term infants) and even 30% higher for infants born at 37 to 39 weeks (early term).[45]

Respiratory

Several studies have shown that late preterm infants have a higher incidence of RDS than term infants.* Wang and colleagues[73] found that late preterm infants, despite their bigger

size and Apgar scores similar to term infants, had increased RDS (28.9% versus 4.2%; odds ratio 9.14, $P < .00001$) and apnea (4.4% versus 0%; $P = .05$) (see Fig. 34-8). In one of the few large, prospective, multicenter studies, the incidence of RDS was 13.7% at 34 weeks, 6.4% at 35 weeks, and 3.3% at 36 weeks of gestation.[58] In a study of 1011 ventilated infants of 34 weeks' or greater gestation, Clark[11] found that RDS (43%) was the most common cause of pulmonary illness, followed by meconium aspiration syndrome (9.7%), pneumonia/sepsis (8.3%), TTN (3.9%), idiopathic PPHN (3.2%), aspiration of blood or amniotic fluid (2.3%), and lung hypoplasia (1.4%). Madar and colleagues[42] found that the incidence of RDS was progressively higher with every week of gestation less than 39 weeks (30 of 1000 at 34 weeks, 14 of 1000 at 35 weeks, and 7.1 of 1000 at 36 weeks).

In a large study cohort of almost 47,000 newborns in California, the incidence of RDS was 22.1% at 33 to 34 weeks, 8.3% at 35 to 36 weeks, and 2.9% at 37 to 42 weeks of gestation.[19] Investigators in another large population-based cohort from California found that the incidence of RDS was 7.4%, 4.5%, and 2.3%, and the need for mechanical ventilation was 6.3%, 3.6%, and 2.3% in 34-week, 35-week, and 36-week infants.[24] In a more recent study, McIntire and colleagues[47] showed that the incidence of RDS requiring mechanical ventilation was 3.3% at 34 weeks, 1.7% at 35 weeks, and 0.8% at 36 weeks of gestation. Another study from St. Louis looking at 1381 infants found that they required respiratory support 30%, 33%, and 23% of the time at 34 weeks, 35 weeks, and 36 weeks.[69]

Prematurity, cesarean section, and absence of labor are independent risk factors for RDS, but together they pose a much greater risk to the infant.* In a Swiss study, Roth-Kleiner and coworkers[59] showed that term and near-term infants delivered by cesarean section before the onset of labor had much higher probability of having severe RDS. Morrison and colleagues[49] also showed that term infants have nearly seven times the odds risk for RDS when delivered by cesarean section without labor, and they showed an increasing incidence of RDS with decreasing gestational age from 41 to 37 weeks. Similarly, in a Dutch study looking at almost 34,000 infants, Hansen and associates[27] found that the relative risk of severe RDS increased with decreasing gestational age even among term infants, with nearly five times the odds at 37 weeks (odds ratio 5, 95% CI 1.6 to 16).

Why is this slightly increased risk of RDS and TTN of concern? Most of these late preterm infants do well and are weaned off respiratory support quickly, but as shown from the above-mentioned studies, a few of them are at increased risk of PPHN, severe hypoxic respiratory failure, and need for extracorporeal membrane oxygenation, putting them at risk of severe morbidity and mortality. Clark[11] showed that nearly 50% of late preterm infants received at least two adjunctive therapies (volume resuscitation, surfactant, vasopressors, neuromuscular blockade, high frequency ventilation, inhaled nitric oxide, extracorporeal membrane oxygenation), and nearly 11% developed chronic lung disease.

Temperature Instability and Hypoglycemia

Cold stress manifests as tachypnea, poor color secondary to peripheral vasoconstriction, altered pulmonary vascular tone, and metabolic acidosis. In a late preterm infant, this condition can worsen respiratory transition and exacerbate hypoglycemia, and these signs can be misinterpreted as something more ominous, such as sepsis, prompting unnecessary interventions and workups. Very few studies have looked at temperature instability in late preterm infants, but from experience, we know that preterm infants are more likely to have hypothermia and cold stress. A survey of rectal temperatures among 196 term infants in a Dallas hospital found that nearly 28% were less than 36.5°C.[39] Similarly, admission temperatures at a Rhode Island hospital NICU in infants weighing more than 2 kg and of greater than 32 weeks' gestation were reported to be between 34.5°C and 36.5°C.[39] Wang and colleagues[73] found that late preterm infants were more likely to present with temperature instability (10% versus 0%; $P < .0012$), and another study found that among late preterm infants admitted to the NICU, hypothermia was listed as the primary reason for admission in almost 5.2% of this group.[69]

---

*References 27, 37, 40, 49, 59, 72.

Hypoglycemia is another component that can affect transition. The incidence of hypoglycemia in preterm infants is three times greater than in term newborns, and nearly two thirds of these infants require intravenous dextrose infusions.[73] Severe hypoglycemia is a well-known risk factor for neuronal cell death and adverse neurodevelopmental outcomes, but the exact threshold for hypoglycemia is not well defined.[23,39] More studies are needed in late preterm infants to define the effects of hypoglycemia, identify at-risk infants, and determine long-term outcomes.

Gastrointestinal Tract

Late preterm infants adapt well to enteral feeds, but have poor oromotor tone and difficulty with sucking and swallowing coordination. Their deglutition, sphincter control, and peristaltic functions are less likely to be as mature as in term infants. One study found that approximately 27% of late preterm infants required intravenous fluids compared with only 5% of term infants (odds ratio 6.48, 95% CI 2.27 to 22.91, $P = .0007$), and among infants requiring prolonged hospital stay, poor feeding was cited as the primary reason in 76% of the late preterm infants.[73] Another study from St. Louis found that among late preterm infants admitted to the NICU, nearly 7.3% of infants of 35 weeks' gestation were admitted for feeding difficulties.[69] In a study of rehospitalizations after birth hospitalization, Escobar and associates[20] found that 26% of the infants were readmitted for feeding difficulties, and late preterm infants were more likely to require rehospitalization (4.4% versus 2% in term infants). Dehydration also exacerbates physiologic jaundice in these infants, predisposing them to rehospitalization and other medical interventions. Whether the immature gut in late preterm infants predisposes them to increased risk of food allergies and diabetes in later life remains to be studied.[56]

Hyperbilirubinemia

Late preterm infants are 2.4 times more likely to develop significant hyperbilirubinemia than term infants.[61] Bhutani and associates,[6] looking at the National Kernicterus Registry, showed that late preterm infants are at increased risk of kernicterus at bilirubin levels equal to or less than that of term infants. They are also more likely to present with high total serum bilirubin levels ($\geq$25 mg/dL), and are less likely to recover without sequelae than term infants. Nearly all late preterm infants in this group were breast-feeding without adequate lactation support and poor milk intake, and they were scheduled a follow-up appointment in 2 weeks.
